THE WHELK DREDGE FISHERY OF DELAWARE

DAVID GARCIA BRUCE*

Division of Fish and Wildlife, Delaware Department of Natural Resources and Environmental Control,
Little Creek Fisheries Laboratory, P.O. Box 330, Little Creek, Delaware 19961

ABSTRACT The status of the Delaware whelk dredge fishery was assessed from state landings reports and from data collected by an onboard observer. Mean annual whelk landings for 1994 to 2000 were 18.5 mt of meats and increased to 241.6 mt for the period 2001 to 2004. Annual landings for 2001 to 2003 were 88% to 119% of the sum of dredge and trawl fishery landings reported by the remaining states on the United States Atlantic coast. Although knobbed whelks, *Busycon carica*, are landed throughout the year, 88% of pooled monthly landings for 1994 to 2004 were taken between March and June inclusive. Eleven observer cruises were conducted March to June 2004. Total estimated daily take of legal (length ≥ 127 mm) knobbed whelks ranged from 1 to 3,710 organisms. Expected catch rates were estimated at 83.2 legal knobbed whelks per hour per meter of dredge width. Dredges were generally towed parallel to bathymetric contours and adjacent to shoal features in 2–20 m depths. Estimates of the area of bottom dredged on each cruise ranged from 4.9–14.2 ha. At times, multiple boats were observed dredging the same bottom, suggesting a cooperative fishing technique. Seventy-nine percent of dredge tows occurred on bottom comprised of mud and sand, and mean numbers of knobbed whelks in 0.04 m³ samples were greatest from mud/sand habitats. Twenty-one taxonomic groups of organisms were observed in samples taken from dredges. Knobbed whelk and horseshoe crabs, *Limulus polyphemus*, dominated dredge catch by number. Whelks collected in the Atlantic Ocean were significantly larger than those collected in the Delaware Bay. Mean lengths of whelks collected in the Bay in 2004 were significantly less than lengths of Bay whelks collected in 1994 prior to the inception of the minimum length regulation. Shifts in size distribution and the cyclical nature of other whelk fisheries suggest that the elevated landings experienced during 2001 to 2004 are not sustainable.

KEY WORDS: knobbed whelk, *Busycon carica*, whelk landings, fishery observer investigation, essential fish habitat, Delaware Bay

INTRODUCTION

Knobbed whelks, *Busycon carica* (Gmelin, 1791) and channeled whelks, *Busycotypus canalicularis* (Linnaeus, 1758), are large gastropods that occupy estuarine and shelf habitats from Cape Cod to Cape Canaveral on the Atlantic Coast of the United States (Edwards & Harasewych 1988). Both species occupy sandy habitats and prey on bivalve mollusks (Magalhaes 1948, Carriker 1951, Davis 1981, Peterson 1982). Colloquially known as conchs, the two species have supported multiple fisheries on the United States Atlantic coast at least since the 1930s (MacKenzie 1997). Channeled whelks are harvested primarily with pot or trap gear, whereas knobbed whelks are most vulnerable to dredge or trawl gear (Eversole & Anderson 1984, Davis & Sisson 1988, Walker et al. 2003, Logothetis & Beresoff 2004).

Mark and recapture studies have demonstrated that knobbed whelk growth is generally slow (Anderson et al. 1985, Kraeuter et al. 1989). Short-term negative growth has been observed (Magalhaes 1948, Anderson et al. 1985), and there are examples of periodic rapid growth (DiCosimo & DuPaul 1985, Kraeuter et al. 1989). Average growth in length of 104 marked whelks in eastern Virginia that exhibited positive growth was 3.2 mm/yr (Kraeuter et al. 1989). Knobbed whelk length at age has been recorded from captive specimens and from examination of annual growth marks identified on opercula. Average length ($n = 20$) of 10-y-old captive eastern Virginia whelks was 144 mm (Castagna & Kraeuter 1994). Eastern Virginia whelks 158 mm long were predicted to be 10 y from operculum age data (age = $-10.99 + 1.33(\text{length})$; $n = 45$, $r^2 = 0.50$, $P = 0.0001$; Kraeuter et al. 1989).

Age or size at reproductive maturity in knobbed whelks has been difficult to determine because gender ontogeny has not been well understood. Phenotypic gender differentiation in whelks is determined by the presence or absence of a penis (Magalhaes

1948, Gendron 1992, Castagna & Kraeuter 1994, Power & Keegan 2001, Avise et al. 2004). In addition to having longer shells than males (Magalhaes 1948, Anderson et al. 1985, DiCosimo & DuPaul 1985, Walker 1988), female knobbed whelks are wider and heavier than males (Anderson et al. 1989). Observations of intertidal mating activity indicate that smaller males and large females successfully produce egg strings (Power et al. 2002). Large females, variable and skewed sex ratios (Anderson et al. 1985), and the presence of male characters in females in at least 12 Buccinidae genera (Power & Keegan 2001) has lead to the hypothesis that knobbed whelks may be protandric hermaphrodites that initially mature as males and then undergo functional sex reversal at larger sizes (Walker 1988). Recent DNA analysis, however, indicates that knobbed whelks are genetically dioecious, having mammalian-like sex chromosomes (Avise et al. 2004); observed phenotypic sex reversal or pseudohermaphroditism, may result from a variety of environmental factors (Jenner 1979).

Whelks have been landed as by-catch or from directed dredge or trawl fisheries from all US Atlantic states except Florida (NOAA Fisheries 2004; <http://www.st.nmfs.gov>). Coast-wide landings from dredge and trawl fisheries have increased from 105.2 mt of meats in 1950, when Federal recording began, to a high of 1913.5 mt in 1994. Although total landings have decreased to 549.8 mt in 2003, ex-vessel price has remained high, as total landings value was \$1.55 million in 2003 relative to \$1.79 million in 1994 (NOAA Fisheries 2004). Whelk meats are generally removed from shells locally and then shipped on ice to northern United States metropolitan areas for canning or fresh retail sale; they are also frozen and shipped to East Asia (Eversole & Anderson 1984, Kaplan & Boyer 1992).

In Delaware, an expanding dredge fishery has raised concern over the long-term sustainability of whelk stocks. Additional attention has focused on by-catch considerations and potential physical effects of dredging activity on ecologically significant benthic habitats, particularly the structures created by the colonial poly-

*Corresponding author. E-mail: david.bruce@state.de.us

chaetes *Sabellaria vulgaris* (Verrill, 1873) and *Hydroides dianthus* (Verrill, 1873). Because of the general lack of published information on mid-Atlantic whelk fisheries, this study presents updated landings information and the results of an onboard fishery observer investigation. Temporal and spatial variation in Delaware landings are described and compared with coastwide landings trends to assess the relative magnitude of the fishery. Direct fishery observations document previously unknown attributes such as gear types, spatial and temporal variation in catch and effort, by-catch composition, and variation in the size structure of Delaware knobbed whelk populations. This work focuses on Delaware's dredge fishery, but contextual comparisons are made with dredge, trawl and pot fisheries in other Atlantic States.

METHODS

Landings Analyses

Landings from the Delaware whelk dredge fishery for 1994 to 2004 were summarized from reports by fishery participants. By statute, Delaware commercial dredging license holders are required to submit monthly catch reports that are archived by the Division of Fish and Wildlife. The information recorded includes number of trips, general location dredged, gear type, the monthly take of knobbed and channeled whelks and whether take was by-catch from other fisheries or from directed whelk fisheries. In addition to requiring monthly logbook reporting, Delaware fishery regulations include the possession of a commercial license, a 127.0 mm minimum length limit for knobbed whelks, a 152.4 mm minimum length limit for channeled whelks and a prohibition of night-time dredging.

Whelk landings are published in biannual summaries of state-wide shellfish harvest and fishery status that date back to 1994 (Whitmore & Greco 2005). Current whelk landings information compiled by the state of Delaware were compared with federally reported coast-wide dredge and trawl fishery landings to assess the relative magnitude of the Delaware fishery. Coast-wide landings data provided by NOAA Fisheries (<http://www.st.nmfs.gov>) do not differentiate knobbed and channeled whelks; therefore for comparative purposes, Delaware landings data used here include both taxa. Delaware landings are reported as total weight including the shell, whereas coast wide landings are reported as weight of edible meats; to allow comparison in equivalent units, Delaware landings were divided by a factor of 3 (Whitmore & Greco 2005). Fishery seasonality was assessed from mean monthly landings and catch-per-unit-effort (CPUE) from Delaware harvest reports 1994 to 2004. CPUE was calculated by dividing monthly harvest in weight by the number of trips reported by each fishery participant.

Onboard Fishery Observation

Eleven observer cruises were conducted on three vessels during March to June 2004 to obtain fishery information not contained in monthly reports. Dredge type, width, ring and mesh size were recorded at the beginning of each cruise. For each dredge tow, start and end times were recorded to determine tow duration and fishing effort. Total daily take, in volume of legal knobbed whelks, was recorded at the end of each cruise. Landed volume was converted to numbers with a conversion factor of 64.37 legal whelks per 0.04 m³ (1.0 bushel). Estimated number of legal whelks was converted to weight with cruise-specific length frequency distributions and a length-weight relationship derived during the cruises (Fig.

Figure 1. Length-weight relationship derived from Delaware Bay knobbed whelks. The dark line represents back-transformed predicted values.

1). The presence of other vessels fishing in the same location was also noted throughout each cruise.

Cumulative catch was recorded at random intervals throughout the latter seven cruises, and was used to estimate catch rates for legal knobbed whelk. To describe catch relative to time fished, catch volume was divided by the total dredge width, thus standardizing gear differences among cruises. A general catch rate estimate was derived with a linear regression model fitted to cumulative catch data from cruises five through nine (PROC REG, SAS 2002).

GPS coordinates were recorded at the beginning and end of each dredge tow. Waypoints were then plotted with Geographic Information Systems (GIS) to identify spatial distribution of fishing activity. Straight tracklines, interpolated from waypoints, were used to represent the path of the dredges. Dredge tracklines were layered upon bathymetry to identify relationships between fishing activity and seabed topography. GIS tools were also used to estimate the area dredged. Buffer polygons were created around intersecting tracklines with a diameter equal to the dredge width, and the total dredge footprint or virgin area dredged on each cruise was estimated from the area of the polygons. Spatial data from Cruises 2, 6, 9 and 10 were not included in areal estimates because the vessel's course frequently did not follow a straight line between waypoints.

At the end of each tow the dredge was brought aboard and contents were dumped on deck. A 0.04 m³ sample of dredge contents was collected before legal-sized whelks were removed. Seabed composition was documented from sample contents and from material attached to dredge gear. All organisms in samples were enumerated to quantify by-catch composition. Knobbed whelk shell lengths were recorded to assess potential spatio-temporal variation in the size structure of the population. Length distributions from Delaware Bay cruises were pooled and compared with lengths from the Atlantic Ocean. Size distribution data collected in the Delaware Bay during 2004 were compared with fishery-dependent data collected in November 1993 and March-April 1994 prior to when the 127.0 mm length limit was imposed. Significant differences in length distributions were identified with the Kolmogorov-Smirnov (KS) test (Proc NPAR1WAY, SAS 2002). Analysis of variance and Tukey tests were used to compare mean

whelk lengths (Proc GLM, SAS 2002); length data were \log_e transformed to satisfy least squares assumptions.

RESULTS

Fishery Landings 1994 to 2004

In addition to the dredge fishery, Delaware has a smaller but significant pot fishery (Table 1). Whelk landings were not recorded by the State until 1994 when legislation was passed regulating all whelk fisheries. Analysis of monthly reports for the period 1994 to 2004 reveal that participation and landings have increased in recent years. The number of license holders that participated in the directed dredge fishery was 11 in 1994, declined to 2 in 1997, and increased to 19 in 2003. Sixteen license holders participated in the 2004 directed fishery (Whitmore & Greco 2005). Landings of pooled knobbed and channel whelks were relatively low for 1994 to 2000 and then increased to high levels in 2001 to 2004 (Fig. 2). The mean annual landing of whelk meats for 1994 to 2000 was 18.5 mt and for 2001 to 2004 the mean annual landing was 241.6 mt (Whitmore & Greco 2005). Except for the blue crab fishery, whelks provide the greatest ex-vessel value of all Delaware commercial fisheries. Dockside ex-vessel value of dredged knobbed and channeled whelks was \$ 574,645 in 2004. Mean annual whelk landings from the Delaware dredge fishery 2001 to 2003 were 96.4% of mean landings for all dredge and trawl whelk landings 2001 to 2003 from the remaining Atlantic states (NOAA Fisheries 2004; Fig. 2). Although Federal coastal fisheries statistics do not differentiate channeled and knobbed whelk landings, State reports indicate that for 1994 to 2004, knobbed whelks comprised between 78.8% and 99.9% of total annual landings by weight in the Delaware dredge fishery. Most fishery effort occurred in the Delaware Bay during 1994 to 2004,

only 3% of 3,031 reported directed trips that landed knobbed whelks occurred in the Atlantic Ocean.

Knobbed whelk landings showed distinct seasonal patterns. Landings from the directed dredge fishery were reported from all months of the 1994 to 2004 period, but the greatest mean total monthly landings occurred from March to June (Fig. 3). For the directed fishery, mean landings of whelk meats for March to June ranged from 12.9–40.2 mt, whereas mean landings for the remaining months ranged from 0.2 mt to 2.7 mt. Mean monthly whelk by-catch landings from the Delaware Bay winter blue crab *Callinectes sapidus* (Rathbun, 1896) dredge fishery ranged from 0.1–2.9 mt. Higher CPUE during March to May suggested seasonally increased vulnerability to dredge gear rather than increased dredging effort (Fig. 3).

Fishery Observations 2004

Catch Between March 15 and June 24, 2004 eleven observer cruises were conducted on three dredge vessels. Two vessels operated from Bowers Beach, DE, and the other from Lewes, DE. Two used single scallop dredges deployed from the stern of deadrise workboats, the other used a motorized bay schooner with paired toothbar crab dredges deployed from the sides. Scallop dredges were 2.62 m and 3.44 m in diameter; bag rings ranged from 63.5 mm to 88.9 mm in diameter; bag mesh ranged from 50.8 mm to 127.0 mm bar measure. Toothbar dredges were 2.3 m wide, rings were 49.0 mm in diameter, and mesh was 127.0 mm bar measure. Fishing effort was directed at whelks on all cruises, but horseshoe crab, *Limulus polyphemus* (Muller, 1785), and blue crab by-catch was retained on Cruise 1 and 3, hard clam *Mercenaria mercenaria* (Linnaeus, 1758) by-catch was retained on Cruise 2.

Whelk dredging began at daylight and ended between 1500 and 1700 h. The general dredge-fishing consisted of towing the gear for approximately 15 min, retrieving the gear, making a 180° turn

TABLE 1.

Coastal Atlantic whelk landings from directed and by-catch fisheries for 2003. Knobbed and channeled whelk landings are pooled. Delaware landings come from monthly logbook reports, whereas landings for the remaining states were reported by NOAA Fisheries.

Figure 2. Reported Delaware whelk dredge fishery landings and fishing effort 1994–2004. Delaware landings are compared with the sum of whelk landings from dredge and trawl fisheries in the remaining Atlantic states 1994–2003 as reported by NOAA Fisheries. Knobbed and channeled whelk landings are pooled, as are landings from directed and by-catch fisheries reporting the use of dredge or trawl gear. Note logarithmic scale on vertical axes.

and releasing the gear again. Dredge tows were oriented in the same direction and intersected. Vessel speed during dredging was between 3.5 and 5.2 kts. Except for Cruises 10 and 11, the total number of dredge tows per cruise ranged between 16 and 38

(Table 2). Whelk catch and effort varied among cooperators. Maximum take of legal knobbed whelk occurred on Cruise 4 and was estimated at 2.03 m³, 1304.1 kg, and 3677 organisms (Table 2). Higher whelk landings were associated with additional vessels

Figure 3. Landings and catch-per-unit-effort (CPUE) seasonality of the Delaware Bay knobbed whelk dredge fishery for 1994–2004. In addition to landings from a directed fishery, whelks are landed as by-catch from the winter blue crab dredge fishery. Note that scales on vertical axes are different.

TABLE 2.

Dredge gear, effort, and landings of legal knobbed whelk (≥ 127 mm) on 11 observer cruises in the Delaware Bay March to June 2004. Horseshoe crab and blue crab were retained on Cruises 1 and 3, and hard clams were retained on Cruise 2.

¹ Common subscript indicates same vessel.

² CPUE = volume (m³) landed/m dredge width/hour dredged.

³ Number of additional vessels dredging same area.

dredging the same area. Catch-per-unit-effort (CPUE) for scallop dredges was 0.009–0.083 m³/m dredge width/hour, mean = 0.04; and for toothbar dredges CPUE was 0.012–0.039 m³/m dredge width/hour, mean = 0.026 (Table 2). The expected hourly catch

rate derived from Cruises 5–9 (Fig. 4) was 0.05 m³ legal whelks/m dredge width. The model used to estimate catch rate was (m³ catch/ m dredge width) = $-0.03 + 0.05 \times \text{hours}$; $P < 0.0001$; $R^2 = 0.90$; $n = 49$.

Figure 4. Cumulative catch of knobbed whelks relative to time towed by scallop and toothbar dredges. Catch in volume is standardized by dredge width to allow comparison among cruises and gears. Data presented here come from cruises 5–11. The expected catch rate derived from Cruises 5–9 was 0.05 m³ of legal whelks per m of dredge width per hour ($\text{m}^3/\text{m} = -0.035 + 0.047(\text{hours})$, $P < 0.0001$, $R^2 = 0.90$, $n = 49$). The inset panel illustrates the late-season decline in catch rates and the cessation of dredging on cruises 10 and 11.

Cumulative catch from Cruises 10 and 11 illustrates why the fishery ceases in late June. On Cruises that occurred prior to 9 June, catch rates remained similar throughout the day (Fig. 4). On Cruises 10 and 11, initial catch rates were similar to previous cruises, but declined after approximately two hours of fishing effort (Fig. 4, inset). Low catch rates and declined efficiency, presumably elicited by increased light levels, prompted both cooperators to cease fishing for the season. June 9 was the last day of dredging for vessel B and June 24 was the last day for vessel C (Table 2); no other boats were observed fishing on either dates.

Fishery Location

Dredge-boat cruises occurred in the Delaware Bay and in the Atlantic Ocean (Fig. 5). Cruises 1–7, 9 and 10 were located in the

Bay between Bowers Beach and Cape Henlopen, DE, and Cruises 8 and 11 were located just off-shore, in the Atlantic Ocean, south of Cape Henlopen. Fishery activity occurred adjacent to the beach in the ocean and on the slopes of the numerous shoals that define Delaware Bay bottom topography. Dredge tracks were generally oriented parallel to bathymetric contours (Fig. 6). Depths recorded during dredge deployment and retrieval ranged from 2 to 20 m. The area of virgin bottom impacted by scallop dredges, estimated from dredge trackline distance and dredge width, ranged from 4.9 ha on Cruise 11–14.2 ha on Cruise 4 (Table 2).

Benthic Habitat Types

Bottom type was recorded from 212 of 274 total dredge tows. Bottom material observed in dredges included mud, clay, sand,

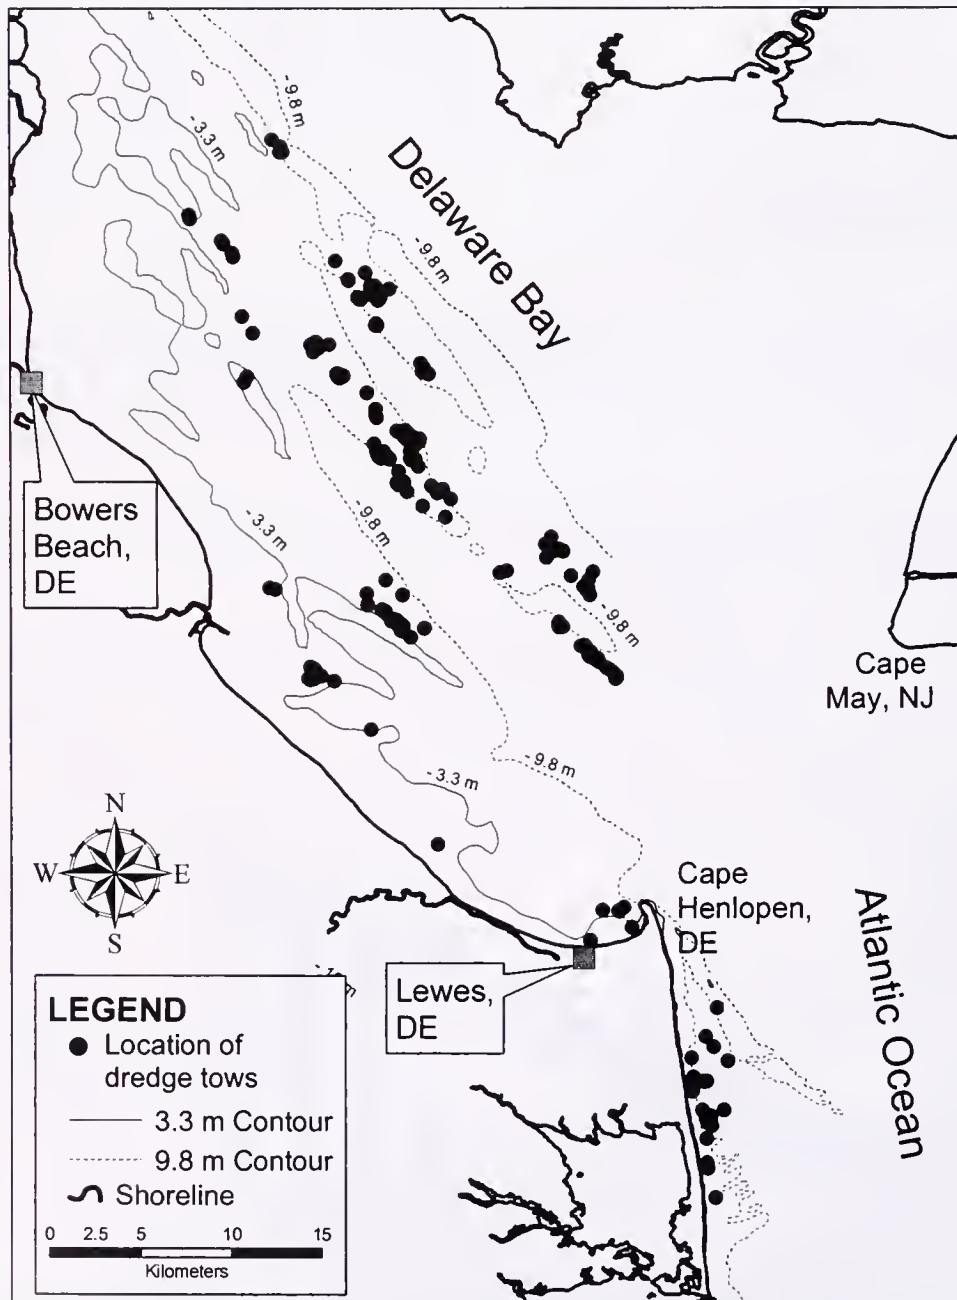

Figure 5. Whelk dredge tow locations recorded from on-board GPS receivers. The parallel Northwest-Southeast orientation of waypoints reflects the orientation of shoal features in the Delaware Bay.

Figure 6. Locations of dredge tracklines relative to bathymetric features at Lower Middle Shoal in the Delaware Bay. GPS coordinates were recorded at the beginning and end of dredge tows. Tracklines are interpolated and assume a straight line between waypoints.

oyster shell, and rock. Less dense material, such as mud, silt and shell fragments may have been washed away during dredge retrieval, and dredges were occasionally rinsed to remove fine sediments, which resulted in potentially ambiguous distinction between Mud/Sand and Sand categories (Fig. 7). Six of the seven bottom categories were characterized by mud or sand components. Knobbed whelks were most frequently associated with mud and sand bottoms. The greatest number of whelks enumerated from 0.04 m^3 samples came from bottoms classed as mud/sand/shell hash (mean = 24.1; standard error = 3.7, $n = 8$); the lowest number of whelks in samples, came from rock/worm tube bottoms

(mean = 1; $n = 1$; Fig. 7). The most frequently recorded bottom category was mud/sand, at 79% of classified tows, and the least frequent was oyster shell/worm tubes at 0.9% of classified tows. Tube casings of the colonial "reef" building polychaetes *S. vulgaris* and *H. dianthus* were observed infrequently, but were generally associated with hard substrates such as rock and oyster shell.

Catch Composition

Proportions of knobbed whelks relative to numbers of by-catch organisms observed in volumetric samples were highly variable. Mean percent knobbed whelk by number was less than 50% on four of the eleven cruises, but ranged up to 88.1% on Cruise 9 (Table 2). Twenty-one taxonomic groups were enumerated from 149 samples taken from dredge contents. The most abundant species in the samples were knobbed whelk and horseshoe crabs (Table 3). Proportions of pooled knobbed whelk by number examined ranged from 31.7% on Cruise 11–88.4% on Cruise 9; for horseshoe crabs proportions range from 1.0% on Cruise 9–41.0% on Cruise 8. The highest proportions of horseshoe crabs by number were observed in samples from ocean Cruises 8 and 11. Knobbed whelks were observed in 98.6% of all dredge tows and horseshoe crabs were observed in 85.2% of all tows (Table 3). Windowpane flounder *Scophthalmus aquosus* (Mitchill, 1815) and unidentified skates were the most evenly distributed taxonomic groups as they were observed in all cruises in similar proportions. Channeled whelk occurred in only 22.2% of the dredge tows sampled and comprised only 1% of organisms observed in samples (Table 3). Proportions of channeled whelk in pooled volumetric samples ranged from 2.9% in Cruise 8% to 0% on Cruise 11; both cruises occurred in the Atlantic Ocean. Although not enumerated in samples, the shells of dead knobbed whelks generally were the most abundant nonliving material observed in dredges, and frequently were more abundant than living whelks.

Figure 7. Fishing effort and numbers of sampled whelks relative to benthic habitat types determined from material on the dredge and associated with dredge contents. Knobbed whelks were enumerated from 0.04 m^3 samples taken from 147 tows. Worm tubes are casings of *Sabellaria vulgaris* and *Hydroides dianthus* polychaetes.

TABLE 3.

Composition of organisms observed in 0.04 m³ samples taken from whelk dredge contents. Counts were pooled from single samples from 149 dredge tows on 11 vessel cruises. Frequency of occurrence is the proportion of samples containing the specific taxon.

Common Name	Latin Name	Number Observed	Percent of Total	Frequency of Occurrence (%)
Knobbed whelk	<i>Busycon carica</i>	2813	63.96	98.66
Horseshoe crab	<i>Limulus polyphemus</i>	802	18.24	85.23
Skate	Rajidae	181	4.11	51.68
Windowpane flounder	<i>Scophthalmus aquosus</i>	120	2.73	43.62
Hard clam	<i>Mercenaria mercenaria</i>	105	2.39	12.08
Spider crab	<i>Libinia</i> spp.	102	2.32	22.82
Rock crab	<i>Cancer irroratus</i>	87	1.98	23.49
Blue crab	<i>Callinectes sapidus</i>	58	1.32	24.16
Channeled whelk	<i>Busycotypus canaliculatus</i>	44	1.00	22.15
Summer flounder	<i>Paralichthys dentatus</i>	37	0.84	14.77
Blue mussel	<i>Mytilus edulis</i>	15	0.34	2.68
Starfish	Asteriidae	9	0.20	4.69
Mud crab	<i>Panopeus</i> spp.	8	0.18	4.03
Oyster toadfish	<i>Opsanus tau</i>	7	0.16	4.03
Hogchoker	<i>Trinectes maculatus</i>	3	0.17	2.01
Striped searobin	<i>Prionotus evolans</i>	2	0.05	1.34
Atlantic moonsail	<i>Polinices duplicatus</i>	2	0.05	1.34
Dogfish	Elasmobranchiomorphi	1	0.02	0.67
Northern pufferfish	<i>Sphoeroides maculatus</i>	1	0.02	0.67
Squid	Teuthoidea	1	0.02	0.67
Total observed =		4398		

Size Distributions of Knobbed Whelk

Shell lengths of knobbed whelk taken from volumetric samples ranged from 66–243 mm (Table 4). Mean lengths ranged from 132.5 mm on Cruise 1–185.9 mm on Cruise 11. Although there were significant differences in \log_e transformed mean length among the cruises ($P < 0.0001$), considering spatial and gear differences among cruises, comparison of means indicate whelks had similar lengths on 7 of the 11 cruises (Table 4). Transformed mean length on Cruise 1 was significantly less than all the other cruises ($\alpha = 0.05$; Tukey's Studentized Range Test). Mean length on Cruise 11 was significantly greater than all the other cruises except Cruise 8, and Cruise 8 mean length was not significantly different from Cruise 5 means ($\alpha = 0.05$; Tukey Studentized Range Test; Table 4). Mean lengths from Cruises 2–4, 6–7 and 9–10 were not significantly different ($\alpha = 0.05$; Tukey's Studentized Range Test). The observed variation in whelk size among cruises may be explained by location, as the two cruises with the largest mean whelk length, Cruises 11 and 8 (Table 4), occurred in the ocean.

Because of length differences observed among individual Bay and Ocean cruises, whelk length data from the Bay were pooled and compared with Ocean length distributions. The 2004 length distribution of knobbed whelks collected in the Bay was generally mound shaped (mean = 148.2, median = 147, standard error = 0.54, $n = 2198$), whereas the length distribution from the Ocean

TABLE 4.

Knobbed whelk length statistics recorded from dredge fishery observer cruises conducted in the Delaware Bay and in the Atlantic Ocean 2004.

Cruise	Location	Knobbed Whelk Length (mm)					Similar Means ¹	n
		Mean	Median	Standard Deviation	Min.	Max.		
1	Bay	132.5	128	22.3	87	192	A	298
2	Bay	145.9	151	22.2	88	187	B	185
3	Bay	145.7	142	22.5	93	211	B	211
4	Bay	146.4	145	28.5	84	221	B	185
5	Bay	173.2	174	27.8	113	223	C	193
6	Bay	149.5	149	19.9	96	204	B	267
7	Bay	147.7	144	22.2	98	209	B	360
8	Ocean	176.7	181	33.8	66	243	CD	175
9	Bay	150.0	149	24.1	91	223	B	394
10	Bay	151.6	153	24.9	91	211	B	105
11	Ocean	185.9	193	25.9	107	222	D	72

¹ Equivalent letters indicate that means of \log_e transformed lengths were not significantly different (Tukey test, $\alpha = 0.05$).

was multimodal and skewed towards greater proportions of larger whelks (mean = 179.4, median = 183, standard error = 2.03, $n = 247$; Fig. 8). Bay and ocean length distributions were significantly different (KS test, $P < 0.0001$). \log_e transformed mean lengths of whelks collected in the Ocean in 2004 were significantly greater than Bay whelks collected in 2004 ($P < 0.0001$).

The relative frequency distribution derived from fishery dependent length data collected from the Bay dredge fishery in November 1993 and May and April 1994 (Michael Greco, Delaware Department of Fish and Wildlife, Little Creek, DE 19961; unpublished data), prior to the inception of the 127.0 mm minimum length limit, was compared with the 2004 Bay distribution (Fig. 8). The two distributions were significantly different (KS test, $P < 0.0001$). Delaware Bay knobbed whelk lengths measured in 1993–1994 (mean = 158.8 mm, median = 147, standard error = 0.64,

Figure 8. Spatial and temporal comparisons of knobbed whelk length distributions from the Delaware dredge fishery. Length data from the Delaware Bay came from 2004 observer cruises 1–7 and 9–10 and from fishery dependent samples collected in 1993 and 1994 prior to the inception of the 127 mm minimum length limit. Atlantic Ocean lengths were recorded on 2004 observer cruises 8 and 11.

$n = 1567$) was intermediate between 2004 Bay lengths and 2004 Ocean lengths. Log_e transformed lengths were significantly greater than 2004 Bay mean length, but less than 2004 Ocean mean length (Tukey's Studentized Range Test, $\alpha < 0.05$). Length variation suggests a temporal shift toward smaller whelks over the last decade (Fig. 8). The proportion of Bay whelks >175 mm declined from 29.4% of the sample in 1993 to 1994 to 17.2% of the sample in 2004.

DISCUSSION

Whelk Fishery Landings

In addition to dredge gear, whelks are landed with trawls, pots, and traps (Table 1). In 2003, pooled landings of knobbed and channeled whelks from all Atlantic dredge/trawl fisheries were 561.3 mt meats, and landings from trap/pot fisheries were 570.1 mt meats (NOAA Fisheries 2004; <http://www.st.nmfs.gov>). The greatest landings from trap/pot fisheries were 224.5 and 91.4 mt meats from the states of Virginia and Delaware respectively; and the greatest landings from dredge fisheries were 262.5 and 163.0 mt meats from the states of Delaware and New Jersey respectively (Table 1).

Over the last decade, landings and effort from the Delaware whelk dredge fishery have exhibited a general increasing trend, but during this period landings from dredge and trawl fisheries the other Atlantic states have declined. Aside from the states of Delaware and New Jersey, the top producing states, Georgia, Maryland, Massachusetts, South Carolina, and Virginia (NOAA Fisheries 2004), are currently experiencing periods of reduced landings (Fig. 9). Whelk landings time series, from 1958 to 2003, indicate that dredge and trawl fisheries generally exhibit abbreviated periods of increased landings followed by longer periods of reduced landings, and that the intervals of reduced harvest may last 1–2 decades (Fig. 9). Because coast-wide landings of knobbed and channeled whelks are pooled, and directed and by-catch fisheries are not differentiated, it is difficult to identify the factors that influence landings cycles. For example, peak landings in Virginia during 1974 to 1975 (Fig. 9) resulted from large landings of channeled whelk by-catch from the surf clam dredge fishery, that coincided with peak surf clam landings (DiCosimo & DuPaul 1985).

Landings variability in whelk dredge and trawl fisheries is determined by a combination of supply, demand, economic costs, or regulatory constraints. In New Jersey, whelks can be harvested as by-catch from the blue crab dredge fishery, and as with any other type of fishery, whelk landings are largely determined by abundance and market conditions (Jeffrey Normant, New Jersey Bureau of Marine Fisheries, Port Republic, NJ 08241; pers. comm.). In Georgia, landings are dependent on whelk abundance, operational costs, and success of the previous shrimp season. The Georgia whelk trawl fishery offers off-season income to the shrimp fleet, and annual shrimp and whelk landings are often inversely related (James Page, Georgia Marine Resources Division, Brunswick, GA 21520; pers. comm.). Similar to the Georgia fishery, landings in South Carolina provide supplemental income to the shrimp fleet during the off-season and fishing effort is dependent on a combination of market value, cost of fuel, and whelk abundance (William Anderson, South Carolina Marine Resources Division, Charleston, SC 29422; per. comm.).

Among the top whelk producing states in the mid and south Atlantic (Fig. 9), Delaware's is the only directed dredge or trawl fishery that has no seasonal restrictions. Maryland has no whelk

season closure, but trawl landings are by-catch from a groundfish trawl fishery (Steven Doctor, Maryland Department of Natural Resources, Matapeake, MD 21666; pers. comm.). In New Jersey, whelks can be landed throughout the year with pot gear, and can be landed as by-catch from the winter blue crab dredge fishery that occurs from mid-November through mid-April (<http://www.state.nj.us/dep/fgw/saltwater>). In Virginia knobbed whelks are landed as by-catch from the blue crab dredge fishery that occurs between December and March in the Chesapeake Bay. Virginia also allows a directed fishery in distinct inshore and off-shore management zones with varying seasonal restrictions (<http://www.mrc.state.va.us/commercialcrabbingrules>). The South Carolina directed trawl fishery occurs between the shrimp fishery closure in January and the reopening in April, and landings are usually highest in the months of March to April. South Carolina whelk seasons may close prematurely if fishery-dependent information identifies low whelk abundance or presence of sea turtles (William Anderson; pers. comm.). The Georgia trawl fishery also occurs during a January to April shrimp closure; premature closure of the whelk season may be influenced by market forces or triggered by the onset of knobbed whelk reproduction identified by the occurrence of egg strings in fishery independent surveys (James Page; pers. comm.).

There is a strong seasonal pattern in landings from the Delaware whelk dredge fishery. Whelks are retained as by-catch from the blue crab dredge fishery that runs from mid-December through March, and are landed by a directed fishery that is open year-round. The highest mean monthly landings, however, occur March to June. High CPUE demonstrates that seasonality in landings may be related to increased whelk vulnerability to dredge gear during March to June. Behavioral information is largely derived from observations of intertidal whelks, but generalizations may be drawn to explain seasonality in CPUE of the subtidal fishery. Intertidal whelks in Georgia were most active during spring and fall (Walker et al. 2004). Released whelks were buried and inactive at 9°C water temperature (January) and were on the surface or partially buried at 13°C water temperature (March); whelks released in the summer initially burrowed up to 14.4 cm into the substrate and then migrated to subtidal areas (Walker et al. 2004). In North Carolina intertidal whelks released in the summer immediately burrowed into sediments and remained so for several days; burrowing behavior was so prevalent that it was termed a vertical migration (Magalhaes 1948).

Whelk activity appears negatively associated with ambient light intensity; during the summer, intertidal whelks were most active at night, during crepuscular periods, or on overcast days (Magalhaes 1948). During December to February subtidal whelks may be sufficiently buried to be less vulnerable to dredge gear (Fig. 3). Although whelks are active in the summer, negative phototaxis may explain intermediate summer CPUE levels. Commercial dredgers in New Jersey report that both knobbed and channeled whelk burrow during the day and capture success is greatest at night or on days with heavy cloud cover (Dobarro 1993). Negative phototaxis during the summer may explain why catch rates on Cruises 10 and 11 declined after approximately 2 hours of dredging (inset Fig. 4), and resulted in a cessation of fishing activity for the season. High CPUE during March–May may result from sediment emergence and increased diurnal activity mediated by increased temperature relative to winter months, and presumably lower light intensity and shorter photoperiod relative to summer months. Although nothing is published on the seasonality in the

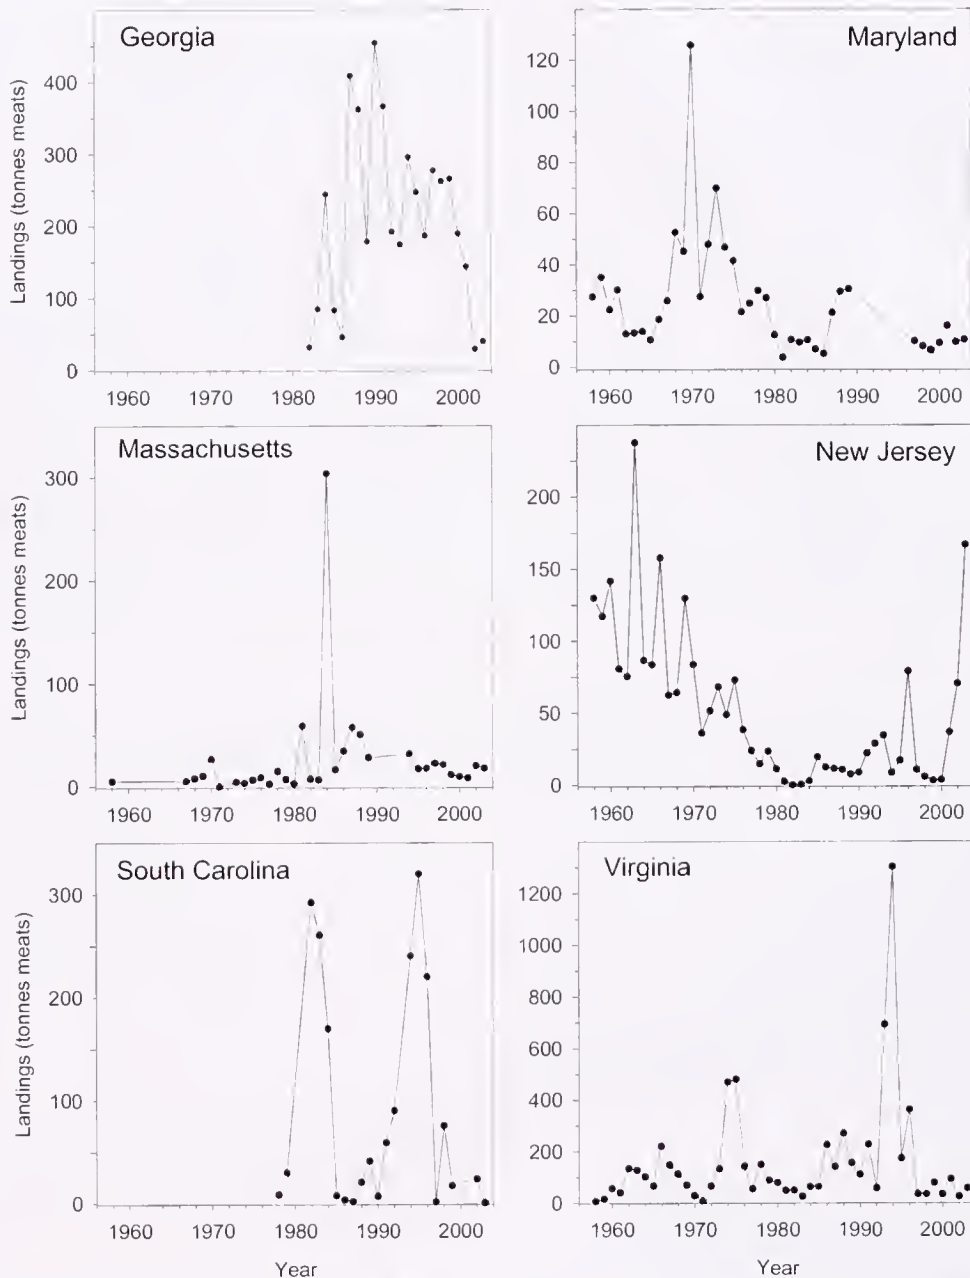

Figure 9. Whelk landings time series reported to NOAA Fisheries by six of the Atlantic states with the highest producing dredge and trawl fisheries. Landings of knobbed whelks and channeled whelks are pooled. Note that vertical axes are not equivalent.

spatial distribution of subtidal whelks in Delaware, high spring-time CPUE may also be related to high densities resulting from affinities to specific over-winter habitats or from premating aggregations.

Gear and Benthic Habitats

Whelk burrowing behavior may explain fishery tactics and the use of specific gear types. Toothbar dredges are the most frequently used gear in Delaware, and are the traditional gear of the winter blue crab fishery. Currently, only three fishermen use scallop dredges, but use of this gear is likely to increase in the future. Unlike toothbar dredges that have 15 cm teeth, scallop dredges use heavy tickle chains to disturb the substrate ahead of the bag. Although catch data was collected from only one toothbar dredger,

CPUE (Table 2) and cumulative catch plots (Fig. 4) suggest that scallop dredges are at least as efficient as toothed dredges for harvesting knobbed whelks. Gears used in other whelk dredge/trawl fisheries include modified shrimp trawls (Anderson et al. 1985, Walker 1988), groundfish trawls and assorted dredges used to collect clams, sea urchins, mussels and oysters (NOAA Fisheries 2003). Dredgers on the New Jersey side of the Delaware Bay are permitted to use toothed crab dredges, dredges with a toothless bar, or a chain in place of the toothed bar (Paul Scarlett, New Jersey Bureau of Marine Fisheries, Port Republic, NJ 08241; pers. comm.). The spatial pattern of dredge deployment in the Delaware fishery is typified by multiple tows over the same area by single or multiple boats. Presumably, dredge track overlap and cooperative dredging enhance catch rates because whelks are at least partially

embedded in the sediment and are not easily dislodged on the first pass. The use of toothbar dredges and scallop dredges with heavy tickle chains also indicate that whelks must be dug from the substrate. In South Carolina, otter trawls are modified with cables and tickler chains that dig whelks from the sediment, and chaffing gear is added to minimize damage to codend webbing (William Anderson; pers. comm.). Because otter trawls must penetrate into the sediment, gear and boat damage is a major economic consideration for entry into the Georgia fishery (James Page; pers. comm.).

Considerable focus has been given to the effect of mobile fishing gear on benthic habitats (National Research Council 2002). Essential Fish Habitat (EFH) considerations relative to ecologically significant habitats were included in recent fisheries legislation (Benaka 1999). So-called "worm reefs" (structure created by the tube dwelling polychaetes *S. vulgaris* and *H. dianthus*), occur in the Delaware Bay (Wells 1970, Haines & Maurer 1980), and have been attributed to having EFH value (NREFHSC 2002, Miller 2001). Increased effort in the whelk dredge fishery over the last decade has raised concern over potential negative effects on Delaware Bay benthic habitats. *H. dianthus* creates a calcareous casing (Haines 1978) and was only observed from dredge tows that contained rock and oyster shell. *S. vulgaris* creates casings of sand grains (Wells 1970) and when observed in dredges, was attached to a variety of hard materials including the shells of living whelks and horseshoe crabs. Material considered to be representative of worm-reef habitat was only observed in seven of 22 analyzed tows on Cruise 2. Cruise 2 was an anomaly relative to the other cruises, because the vessel targeted hard clams in addition to whelks and the captain wanted to demonstrate the spatial distribution and variability of benthic materials to the observer. Because *H. dianthus* and *S. vulgaris* only colonize hard substrates (Wells 1970, Curtis 1975, Tinsman & Hense 2004), worm-reef habitat is generally not dredged by the whelk fishery because of the difficulty of culling relatively few whelks from heavy nonliving material and potential damage to gear. Because most fishery effort and whelk catch comes from mud and sand habitats, it appears that the dredge fishery has a negligible effect on worm reef habitats. The cumulative effect of dredge fishery activity on mud and sand habitats, however, is unknown.

Catch Composition

A variety of organisms were observed in whelk dredge samples and ratios of whelks to by-catch varied within and among observer cruises. Temporal, spatial, and gear variability presumably contributed to differences in catch composition. The highest variability on the proportion of knobbed whelks to by-catch was observed during Cruise 2 (Table 2), and is demonstrated by high proportions of hard clams and horseshoe crabs, and by fishing effort expended on a variety of bottom types, such as tube worm habitat, that held relatively few whelks. Ninety-three percent of all hard clams and 19% of horseshoe crabs enumerated in Delaware Bay samples came from Cruise 2. Variability in Cruise 2 catch composition occurred because hard clams were targeted in addition to whelks, and the captain chose to dredge a variety of bottom types. Proportions of knobbed whelks in samples were also low on cruises that were conducted in the Ocean. Lower numbers in volumetric samples from Cruises 8 and 11 may be explained by larger size of ocean whelks (Fig. 8) and by high levels of horseshoe crab by-catch. Taxa observed as by-catch in whelk trawl fisheries include Atlantic croaker *Micropogonias undulatus* (Linnaeus, 1766), sting

rays *Dasyatis* spp., horseshoe crabs, blue crabs and spotted seatrout *Cynoscion nebulosus* (Cuvier, 1830) in South Carolina (William Anderson; pers. comm.); and fringed flounder *Etropus crossotus* (Jordan & Gilbert, 1882), Atlantic stingray *Dasyatis sabina* (Lesueur, 1824), star drum *Stellifer lanceolatus* (Holbrook, 1855), southern stingray *Dasyatis americana* (Hildebrand & Schroeder, 1928), and southern kingfish *Menticirrhus americanus* (Linnaeus, 1758) in Georgia (James Page; pers. comm.).

The scarcity of channeled whelks in dredge samples is congruent with the observations of others that knobbed whelk dominate landings from dredge and trawl fisheries (Anderson et al. 1985, Davis & Sisson 1988) and channeled whelks dominate landings from pot or trap fisheries (Davis & Sisson 1988, Walker et al. 2003, Logothetis & Beresoff 2004). The absence of knobbed whelks in pots may be explained by a preference for live bivalves rather than bait and carrion, and potentially a reduced ability to enter traps because of a heavier shell than the thinner-shelled and more active channeled whelk (Davis 1981, Sisson & Wood 1988, Dobarro 1993, Walker et al. 2003, Logothetis & Beresoff 2004). Channel whelks have been documented as being less diurnally active than the knobbed whelk (Magalhaes 1948). During daylight, channel whelks may be sufficiently buried to be invulnerable to dredge gear.

Size Distributions

Analysis of knobbed whelk size distributions from 2004 revealed that mean lengths were relatively similar among cruises in the Bay, but whelks from the Ocean were larger than those from the Bay. Delaware landings reports for 1994 to 2004 reported that only 3% of 3,031 dredging trips occurred in the Ocean. Log-book reports from 2004 indicate that 5% of 478 trips occurred in the Ocean. Lower levels of fishing effort and exploitation in the Ocean may explain spatial differences in size distributions. Observed differences between whelks collected in 2004 and whelks collected in 1993 to 1994, when there was no minimum legal length, suggest that the size distribution in the Bay has shifted to smaller individuals over that last decade. Length data from 2004 were recorded on-board prior to culling, whereas 1993 to 1994 data were recorded from landed whelks. Although there was no minimum legal length in 1993 to 1994, it is possible that smaller whelks were collected, but were culled and not landed. Regardless, the mode at 190 mm observed in the 1993 to 1994 distribution (Fig. 8) was absent in the 2004 length distribution. Increased exploitation (Fig. 2) may explain shifts in Bay size distributions over the last decade.

There is evidence that declines in annual whelk landings may result from over-harvest. Declines in catch and size of pot-caught channeled whelk in New England has been attributed to increased fishing pressure (Davis & Sisson 1988). The South Carolina trawl fishery experienced record landings in 1982 followed by precipitous declines in 1983 to 1984 (Fig. 9). Landings declines were attributed to high and sustained levels of fishing effort by South Carolina trawlers, coupled with low growth rates and confined home ranges of knobbed whelk determined from mark and recapture studies (Anderson et al. 1985). Presently, the United States South Atlantic whelk fishery is considered to be over-fished and overall annual landings are expected to remain low (Burrell 1997).

Landings from Delaware and New Jersey dredge fisheries are the highest on the Atlantic Coast (Figs. 2 and 9). In Delaware more whelks are landed from the Delaware Bay than from the Atlantic Ocean. Although whelks are also dredged from New Jersey's

coastal bays, a good portion of the whelks harvested by dredge that are landed in New Jersey come from the Delaware Bay (Jeffrey Normant; pers. comm.). Because of the magnitude of fishery activity in the Delaware Bay, it appears that whelk productivity in the Bay has been relatively high. The presence of sublegal whelks in commercial gear (Fig. 8) indicates that successful recruitment occurs. Despite increased fishery activity, whelk densities may remain elevated in some locations. For example, during Cruise 4, an estimated 3,677 legal whelks were taken from an approximately 14.2 ha area. If all 13 boats observed fishing the same bottom that day (Table 2) maintained an equivalent catch rate, the estimated density would be 3,354 legal whelk per ha or approximately 1 whelk per 3 m².

Landings time series among the top-producing dredge and trawl fisheries in the Atlantic states reveal a general pattern of years of large landings followed by multiyear periods of smaller annual landings (Fig. 9). Delaware landings data (Fig. 2) suggest that the fishery is at a peak in the cycle as landings and effort have

been consistently high over the last four years relative to the 1994 to 2000 period. Demand for domestic whelk meats appears to be consistently high and is partially driven by depletion of global whelk fisheries (Kaplan & Boyer 1992); thus current effort levels in the Delaware fishery will continue until profitability declines. Given the experiences of other states and an apparent inability of whelk populations to sustain elevated exploitation for extended periods, the Delaware dredge fishery should expect reduced landings in the future.

ACKNOWLEDGMENTS

The author thanks the captains and crews of cooperating dredge vessels for accommodating an observer and allowing this work to be done; Craig Shirey, Roy Miller, Rick Cole and anonymous reviewers for comments on various manuscript drafts and William Anderson, Steven Doctor, Jeffrey Normant, James Page and Paul Scarlett for providing information on other whelk fisheries.

EFFECTS OF DIETS, THEIR CONCENTRATIONS AND CLAM SIZE ON FILTRATION RATE OF HARD CLAMS (*MERETRIX LUSORIA*)

YEW-HU CHIEN* AND WEN-HUA HSU

Department of Aquaculture, National Taiwan Ocean University, Keelung, Taiwan 202, Republic of China

ABSTRACT The hard clam (*Meretrix lusoria*) is one of the most important cultured molluscs in Taiwan. Although it is mainly cultured in ponds and supplemental feeding of artificial feed is commonly practiced, no scientific information on its preferred foods and appropriate feeding strategies are available. Six diets: fishmeal (F), soybean meal (S), commercial hard clam feed (C), microalgae *Tetraselmis chui* (T) and *Nannochloropsis oculata* (N) and bread yeast (Y), were fed to hard clams. Each diet was fed at 3 concentrations (20 mg L⁻¹, 200 mg L⁻¹ and 633 mg L⁻¹) and was fed to clams of 3 sizes (7–11 g, 12–17 g and 18–26 g total body weight) to gauge their effects on weight-specific filtration rate and pseudofeces production. Overall, the filtration rates for diets in descending order were S > C > F = Y > N > T. Particle size of the diets played an important, but not the only, role in determining the filtration rate. Diets with regular particle shape (N, T, Y) yield lower filtration rates and higher pseudofeces production than diets with irregular shape (C, F, S). Both filtration rate and pseudofeces production were higher for yeast than for algae (T, N). Filtration rate and pseudofeces production were also higher for the mixed component diet (C) than for single component diets (F, S). Filtration rate, but not pseudofeces production, was higher for the plant-based diet (S) than for fishmeal (F). Both diet concentration and clam size had inverse correlations with weight-specific filtration rate. The effects of all interactions between diets, diet concentrations, and clam sizes on filtration rates were significant, reflecting the complexity of feeding behavior of *Meretrix lusoria*.

KEY WORDS: clam, *Meretrix lusoria*, filtration rate, pseudofeces, commercial feed, microalgae, fishmeal, soybean meal

INTRODUCTION

The hard clam (*Meretrix lusoria*) is one of the most important cultured molluscs in Taiwan. Its reported peak culture area was 7,552 ha in 1994, peak production was 31,517 t in 2003, peak productivity was 4.85 t ha⁻¹ in 2002 (Fig. 1). Hard clams were introduced to the northern coast of Taiwan from Japan in 1925 and later extensively ranched in sandy tidal flats, especially on the west coast. Before 1970, hard clams were cultured in ponds (Chen 1984) although it is unknown when this activity first started. In 1980, pond-culture accounted for only 13% of the total culture area. Hard clams were mostly cultured on sandy tidal flats. After mass artificial propagation was achieved (Chen & Lyuu 1982), total production increased 74% from 9,200 t in 1982 to 16,049 t in 1983 but also the importance of pond-culture. In 2003, around 83% of the culture area was in ponds and 94% of the production was from ponds.

Various artificial diets, either as supplements or as the main food source for larval, juvenile and adult bivalves have been developed, which include dried algae (Laing et al. 1990, Gladue 1991, Laing & Gil Verdugo 1991, Laing & Millican 1992), preserved algal pastes (Donaldson 1991), microencapsulated diets (Jones et al. 1984, Langdon et al. 1985) and yeast-based diets (Epifanio 1979, Urban & Langdon 1984, Coutteau et al. 1990, 1991). Such feeding, conducted either experimentally or commercially, however, was mostly done in hatcheries or nursery ponds (Southgate et al. 1998), not in growout ponds. In Taiwan, feed accounted for 14% to 37% of total production cost of pond-cultured hard clam (Guo 2003). There are two feed mills in Taiwan producing formulated hard clam feed, which is used by some farmers.

Hard clams have much higher productivity when cultured in ponds than when ranched in sandy tidal flats. In 2003, productivity in the former, 5,480 kg ha⁻¹, was 2.2 times higher than that in the latter, 1,710 kg ha⁻¹ (Fisheries Administration 2003). In addition,

higher stocking densities are used in growout ponds: 1.00 to 1.60 million seed clams (0.8–1.0 g) ha⁻¹ versus <1.00 million seed clams ha⁻¹, and faster growth occurs in ponds: 6–8 mo versus 1 year to reach marketable size (20 g total body wet weight) (Chen 1984). Organic fertilization with rice bran, chicken droppings, hog manure, and supplemental feeding contribute greatly to the food supply in ponds (Ho 1991). In Taiwan, food organisms used in hatcheries or nursery ponds include the algae *Isochrysis* sp., *Platymonas* sp., yeast and photosynthetic bacteria *Rhodospirillum* sp. Supplemental foods used for hard clam growout ponds include fishmeal, fish soluble, soybean meal, commercial formulated food and other home made mixtures in powder form. Clam farmers develop their diets and feeding strategies, such as the amount and timing of food delivery and assess the feeding effects on environmental quality completely based on their own experience, without using the available information from scientific studies. Therefore, this study aims to determine the effects of various concentrations of six diets that are currently or could potentially be used for hard clam aquaculture, on filtration rate and pseudofeces production of hard clams of different sizes so that this basic information can be used to develop compound feed formulation and appropriate feeding strategies.

MATERIALS AND METHODS

Experimental Variables: Diets, Their Concentrations and Clam Sizes

The 6 experimental diets evaluated were fishmeal (F), soybean meal (S), commercial hard clam formulated feed (C), live microalgae: *Tetraselmis chui* (T) and *Nannochloropsis oculata* (N) and bread yeast (Y). The major ingredients in C are S, F, Y, squid meal, corn meal, oyster shell, yeast and calcium perphosphate. The algae T and N were often found in hard clam ponds during our field observations and have been widely used as feed for bivalves (Laing & Gil Verdugo 1991, Laing & Millican 1992). The feed components F, S, Y and C were obtained from a commercial source (Taishan Co., Sahu, Taichuan, Taiwan). Microalgal stock cultures were obtained from Biotechnology Section, Taiwan Fish-

eries Research Institute. These algae were cultured in 5-L glass flasks containing Provasoli's enriched seawater (35‰ salinity, 0.45 μm filtered and UV treated) (Provasoli 1968). Cultures were held at 25°C under cool white fluorescent light on a 12 hL:12 hD photoperiod. Algae were used during mid stationary phase of growth. The diet F and S were further ground by a locally made feed ingredient grinder for 4 min and 8 min, respectively to obtain finer particles sizes. Particle sizes were determined by measuring at least 300 diet particles to the nearest 5 μm with a hemacytometer under a microscope (Nikon E400, Tokyo, Japan). Intervals were set: <5 μm , every 5 μm from 6–30 μm and >30 μm . Particle sizes (mean maximum length \pm standard deviation) and shape (determined qualitatively) of the experimental diets were: F = 17.3 \pm 7.5 μm , irregular; S = 19.5 \pm 10.2 μm , irregular; C = 12.5 \pm 6.3 μm , irregular; T = 8.0 \pm 1.5 μm , oval; n = 4.1 \pm 0.7 μm , round and Y = 6.2 \pm 1.0 μm , round.

The diet concentrations used were determined by using the maximum concentration of *N. oculata* that could be cultured in this laboratory, around 2,000 mg dry biomass L^{-1} , as 2 units in a \log_{10} scale. We then chose 0.5, 1 and 1.5 units as the concentrations for use, which were equivalent to 20 mg, 200 mg and 633 mg dry weight L^{-1} . In clam ponds studied, algal concentration could reach as much as 435 mg dry weight L^{-1} depending on their productivity.

Dry weights of algal cells of both species were determined by filtering algae from a 100-mL aliquot of suspension of known concentration; aliquots were taken from five replicate cultures of each species. Algae were retained on tared, glass-fiber filters (Whatman, no. GF/F, 0.7- μm pore size), which were subsequently washed with a 0.5 M solution of ammonium formate to remove sea salts. Filters were then dried at 100°C for 2 h to volatilize the

ammonium formate (Epifanio & Ewart 1977) and weighed on an analytical balance to a precision of 0.1 mg. Algal density in dry weight base were 1.18 (± 0.43) $\times 10^8$ cells mg^{-1} and 1.85 (± 0.67) $\times 10^7$ cells mg^{-1} for N and T, respectively.

Three size classes of clam were used: small, 7–11.9 g (total body wet weight); medium, 12–17.9 g and large, 18–26 g. Clams were obtained from ponds in Taishi station, Mariculture Research Center, Taiwan Fisheries Research Institute. At our laboratory, they were acclimated for a week under ambient temperature in a 2,000-L fabricated reinforced polyethylene (FRP) round tank paved with 6–10 cm sand, and fed a combination of all 6 diets on an equal dry weight basis. Salinity was maintained at 15‰ to 18‰, which was the salinity in the ponds where the clams were from. One day before experimentation, an adequate number of clams were collected and placed in a 20-L bucket filled with 1- μm filtered seawater. Water temperature was controlled at around 25.2°C \pm 0.4°C and clams were not fed.

Standard Curve of Suspended Particles

A turbidity-weight relationship was developed to estimate the biomass of each diet in the water. Five concentrations: 20 mg, 63.3 mg, 200 mg, 633 mg and 2,000 mg L^{-1} of F, S, C and Y suspension were obtained by weighing 0.012, 0.038, 0.12, 0.38 and 1.2 g of each diet into a beaker containing 600 mL filtered seawater and suspended with a magnetic stirrer. A 10-mL sample was taken by pipette and immediately measured in a turbidity meter (HACH 2100P, Loveland, Colorado, USA). For each concentration, 5 replicates were measured and for each replicate, 2 repeated readings were obtained. For the microalgae, instead of dilution, the original algal suspension was concentrated several times by centrifugation at $\times 3,000$ rpm for 10 min each time to obtain a calibration.

Filtration Rate Apparatus

Clearance rates were determined using methods similar to those of Shumway et al. (1985) and Levinton et al. (2002). Filtration rate was determined by the indirect method (Epifanio & Ewart 1977, Winter 1978), measuring the removal of suspended particles from a known volume of water per unit time (Fox et al. 1937). This "indirect method" agrees well with other indirect and direct methods used for measuring filtration rates in mussels (Famme et al. 1986). The feeding apparatus was composed of a 1-L beaker held over a magnetic stirrer (MS-90, Fargo). The beaker contained a feeding platform, set above a 3-cm Teflon stirrer, made by tying three 3.5-cm rods perpendicularly to a 6-cm ring. Both ring and rods were made of no. 19 gauge (1.9 mm inner diameter) insulated wire. The ring was covered with a 2 mm \times 2 mm mesh nylon net. The dial of the stirrer was fixed at 3.5 so that mixing kept all diet particles in suspension but would not resuspend the clam's fecal material. One clam was used per beaker.

Each trial was conducted as follows: a designated diet suspension was prepared and 600 mL of diet suspension was poured into a 1-L beaker. The stirrer was activated and a designated size clam, which had been starved for 24 h, was placed on the center of the feeding platform. A 10-mL sample of suspension was collected to measure the initial diet concentration. The experiment ran for 1 h starting when the clam resumed feeding and extended and dilated its siphon. Another sample was taken at the end of the hour for the final diet concentration. In a few preliminary trials, when large size clams were used to test their filtration capability in diet F and S at a concentration 20 mg L^{-1} for 10 and 15 min, no significant

reduction in diet concentration were found. In a similar clearance experiment, Levinton et al. (2002) used a clearance period of 0.75 h for mussels and 1.5 h for oysters, thus we chose 1 h for each trial. Experimental bivalves were then opened; their soft tissue was separated from the shell, blotted with a paper towel and then dried at 105°C for around 48 h until a constant weight was reached. Dry weight data were used to calculate weight specific filtration rate.

Considering the deviation of experimental conditions from the natural ones, such as starvation prior to the measurement, constant circular flow around the clam and clam's laying position on the feeding platform, filtration rate determined by this indirect method may not be very representative of the true filtration rate of this hard clam in natural conditions. However, for the simplicity of our method, apparatus set-up and the consistency in use, the filtration rate should potentially be used in a comparative manner among treatments.

Filtration Rate Experiment

A $3 \times 6 \times 3$ factorial arrangement treatments design was used in which three sizes of clam were exposed to six diets each at three concentrations. Each treatment combination had four replicates. Each replicate used 3 feeding chambers: a blank chamber using a dummy clam and two treatment chambers with live clams. The dummy clam consisted of an empty clam filled with sand with the shells glued together. In each replicate the clams had a similar shell size. The experiments in three chambers of a replicate were run simultaneously. After correcting by turbidity changes in the blank chamber, the two readings for live clams were averaged and used as one datum for that replicate.

The equation by Riisgård (1988) was used to estimate the filtration rate (F):

$$F = V/t \times \ln Co/Ct$$

where V is a known volume of water; t the time in h; ln the natural logarithm; and Co and Ct the particle concentrations at time 0 and t, respectively. Because the rate of filtration of bivalves is related to the size of the animal (Winter 1978) and clam weight varied for each trial, weight-specific filtration rate ($FR = F/W$ in $\text{mL h}^{-1} \text{g}^{-1}$) (Epifanio & Ewart 1977) was used: where W was dry weight of soft tissue mass (g) (Bayne et al. 1976).

Pseudofeces Production Experiment

A factorial treatments design: diets 6×2 clam sizes were used in which each treatment had four replicates. Only 1 diet concentration was used, 200 mg L^{-1} . This was because some of the clams would not feed at $633 \text{ mg dry weight L}^{-1}$. On the other hand, at the lowest concentration, 20 mg L^{-1} , insufficient pseudofeces could be collected to allow accurate measurement. No medium size clams were available when conducting the experiment so only small and large clams were used.

After feeding for 1 h, the clam was removed from the beaker. A pipette was used to carefully collect the pseudofeces on the bottom or attached to the wall of the beaker or that clung to the feeding platform. They were placed in an aluminum foil plate (5 cm in diameter and about 1.9 g weight), dried to constant weight at 80°C and weighed to the nearest 0.01 mg.

Statistical Analysis

For filtration rate, a 3-way ANOVA was used to test the significance of the main effects and interactions of diets, diet con-

centrations and clam sizes. For pseudofeces production, a 2-way ANOVA was used to test the significance on the main effects and interactions of diets and clam sizes. Duncan's multiple range tests (DMRT) were used to test the differences among the levels of each main effect. Besides DMRT for pairing (one-to-one) comparisons, 5 orthogonal contrasts were conducted for systematic (set-to-set) comparisons: (1) diet particle shape: regular (N, T and Y) versus irregular (C, F and S); (2) regular particle shape: algae (N and T) versus yeast (Y); (3) algae: N versus T; (4) irregular particle shape: mixture components (C) versus single component (F and S) and (5) single component: plant material (S) versus animal material (F).

RESULTS

Filtration Rate

There were highly significant ($P \leq 0.01$) effects of diet, diet concentrations and clam sizes on filtration rate, and all the interactions were highly significant (Table 1). Within diet, orthogonal contrasts (Table 1) indicated that the average filtration rate for diets having regular shape of particles (i.e., N, T and Y) was significantly lower than that for diets having an irregular particle shape (i.e., C, F and S). For the regular particle shape diets, average filtration rate for the planktonic algae N and T was significantly lower than that for the yeast, Y. Between the two algae, clams fed N had significantly higher filtration rates than those fed T. For the irregular particle shape diets, filtration rate for the diet having mixed components (i.e., C) was significantly lower than the average filtration rate for diets having a single component F and S. Between the diets that had a single component, clam filtration rate of S was significantly higher than that of F. Disregarding clam sizes, DMRT results showed that the filtration rates in descending order were $S > C > F = Y > N > T$ (Fig. 2). For small clams, all differences in filtration rate among diets were significant (i.e., $S > C > F > Y > N > T$). However, for larger clams, the differences in filtration rate among diets became less distinct. For example, for large clams, there were no differences in filtration rate between S and F, and also no differences among S, Y and C.

Overall, filtration rate decreased with increasing diet concentration (Fig. 3). Such an inverse relationship was especially evident between diet concentration 633 mg L^{-1} and 200 mg L^{-1} and this effect was consistent for each clam size class (i.e., whereas the former diet concentration was about 3 times as the latter, the filtration rate at the former was about 1/3 of the latter).

Disregarding diet and diet concentration, the smaller the clam, the higher the weight-specific filtration rate. The filtration rates differed significantly and were 49 ± 2 , 30 ± 1 and $27 \pm 1 \text{ mL h}^{-1} \text{g}^{-1}$ for small, medium and large clams, respectively.

Pseudofeces Production

There were highly significant effects of diet and clam size on pseudofeces production. No interaction was found between diet and clam size on pseudofeces production (Table 2). Overall, large clams produced significantly less pseudofeces ($1.3 \pm 0.9 \text{ mg g}^{-1}$) than small clams ($1.7 \pm 0.8 \text{ mg g}^{-1}$).

Within the diet effects, orthogonal contrasts (Table 2) indicated that the average pseudofeces production from diets having a regular particle shape (i.e., N, T and Y) did not differ from that of diets having an irregular particle shape (i.e., C, F and S). For the diet with a regular particle shape, average pseudofeces production from

the two planktonic algae N and T, was significantly lower than that from the yeast Y. Clams fed on N produced significantly less pseudofeces than those fed on T. For the diet with irregular particle shape, pseudofeces production from the mixed diet (i.e., C) was significantly lower than that from single-component diets (i.e., F and S). Between the single-component diets, the pseudofeces production from S was not different from that of F. Among-diet effects showed that for clams of both sizes (Fig. 4), those fed on Y produced the highest amount of pseudofeces. Among the remaining diets, pseudofeces production descended in the following order: $S \geq F \geq T \geq C \geq N$. Pseudofeces production for F, T and C did not differ significantly. When DMRT was performed by clam size separately, the order for large or small size classes remained the same as for both sizes combined. The only difference in DMRT results between large and small clams was that for the latter Y was not significantly greater than S but for the former pseudofeces production differed significantly between these two diets.

DISCUSSION

In general, suspension-feeding bivalve molluscs have adopted several strategies for controlling the ingestion of particulate matter (MacDonald & Ward 1994), including regulation of (1) feeding duration (Foster-Smith 1975); (2) clearance rates (Bayne & Newell 1983) and (3) pseudofeces production (Kiorbø et al. 1980, Newell & Jordan 1983). Various criteria are often proposed as the basis for particle selection including physical features: such as particle size (Tammes & Dral 1955, Möhlenberg & Riisgård 1978, Riisgård 1988, Langdon & Newell 1990), shape (Bayne et al. 1977), aggregation (Waite et al. 1995), motility and density (Brilliant & MacDonald 2000), chemical cues: such as energy content, C/N ratio (Ward & MacDonald 1996), organic content (Bacon et al. 1998, Defossez & Hawkins 1997) and chlorophyll content (Nakamura 2001). The production of pseudofeces can serve to improve the quality of material ingested by means of selective rejection, rather than simply the elimination of excess material of the ingestive capacity (MacDonald & Ward 1994). Selective rejection

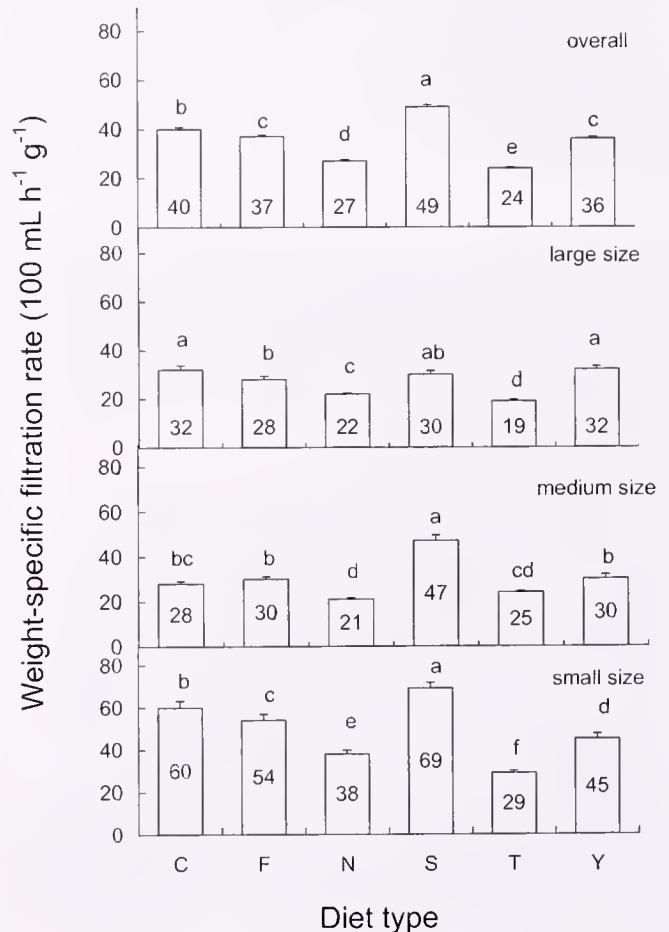

Figure 2. Average filtration rate of 3 sizes of hard clams receiving 6 diets (C; commercial hard clam feed, F; fishmeal, N; microalgae *Nannochloropsis oculata*, S; soybean meal, T; microalgae *Tetraselmis chuii*, and Y; bread yeast). Averages not sharing any common alphabet (above data column) are significantly ($P \leq 0.05$) different.

Figure 3. Average filtration rate of 3 sizes of hard clams receiving 6 diets at 3 concentrations. Averages not sharing any common alphabet (above data column) are significantly ($P \leq 0.05$) different.

mainly involves preferential rejection of nonchlorophyll-containing particles (Kiorbøe & Möhlenberg 1981, Newell & Jordan 1983) and reduction of the proportion of particulate inorganic matter in pseudofeces (Widdows et al. 1979, Kiorbøe et al. 1980, Kiorbøe & Möhlenberg 1981, Bricelj & Malouf 1984, Defossez & Hawkins 1997).

Diets

The highest filtration rate obtained for soybean meal in this study (Fig. 2) could be mainly attributed to its having the largest particle size, which made S easier to be retained by the gill of clam and left less particles in water. Previous studies have demonstrated the importance of particle size in mediating selection processes in some bivalve species (Defossez & Daguzan 1996, Defossez & Hawkins 1997). Wisely and Reid (1978) considered the selection of feed by members of the order Eulamellibranchia (oysters, cockles and clams); selection appeared to be made on the basis of particle size regardless of potential food value. In *Mytilus edulis*, *Cerastoderma edule* and *Venerupis pullastra*, the rates of ingestion of particles were found to be roughly proportional to the size of the particles (Foster-Smith 1975). A few studies indicated that bi-

valves had higher filtration or retention efficiency for larger particles. The filtration efficiency of bacterioplankton (0.2–2 μm) by *Geukensia demissa* was 42% lower than that of phytoplankton >2 μm (Wright et al. 1982). *Mercenaria mercenaria* completely retained particles above 4 μm . Below this size threshold retention efficiency gradually decreased to between 35% and 70% for 2- μm particles (Riisgård 1988). In the clam *Ruditapes decussatus* particles smaller than 3 μm in diameter, which include bacteria and clay particles, were retained with low efficiency (i.e., <75%). Algal cells, such as phytoplankton and other particles in the size range 3–8 μm were efficiently retained (70% to 100% retention) by the clam (Sobral & Widdows 2000). The studies mentioned earlier concluded that filtration retention efficiency increased with increasing particle size from 0.2–8 μm . In our study, because the particle size of diets varied over a wider range, 4 μm to 19 μm , the overall ranking of filtration rates for the diets ($S > C > F = Y > N > T$, Fig. 2) did not completely follow the ranking of particle size: S (19 μm) > F (17 μm) > C (12 μm) > T (8 μm) > Y (6 μm) > N (4 μm). Bacon et al. (1998) indicated that because most of the particles used in their study were between 4 and 6 μm in diameter, size-dependent selection was probably not a significant factor and selection by the softshell clam *M. arenaria* was based on organic content, or perhaps other qualitative particle characteristics.

That particle size that can affect pseudofeces production is indicated by the comparison of the two algae T and N; the higher pseudofeces production when clams were fed on T may be attributed to the fact that T particles are twice as big as N particles or to other confounding factor. Similarly, Defossez and Hawkins (1997) experimented with the mussel *Mytilus edulis* and clams *Ruditapes philippinarum* and *Tapes decussatus* and they concluded that particles with diameters larger than from between 7.5 and 22.5 μm were preferentially rejected as pseudofeces. As with filtration rate, particle size was not the only factor affecting pseudofeces production. In our study, pseudofeces production in descending order was $Y > S \geq F \geq T \geq C \geq N$ (Fig. 4), which again did not follow completely the order of particle size. The result that particle selection via pseudofeces production was not totally based on the size, was in agreement with MacDonald and Ward (1994).

The results of the orthogonal contrast indicated that the average filtration rate for diets with a more regular particle shape (i.e., N, T and Y) was significantly lower than that for diets consisting of irregular particle shape (i.e., C, F and S). Few studies have been published on the effects of shape regularity of diet particles on filtration rate in bivalves. Bayne et al. (1977) pointed out that elongated or triradiated algal cells might be more efficiently retained than spherical particles of the same volume. Wisely and Reid (1978) mentioned that rice particles that were used in their study, when viewed microscopically, were mainly irregularly shaped but many of them had a characteristic "hexagonal" appearance. Irregular shape may not only extend particle size in one dimension but the rough extrusions may also favor the retention of particles by the gill and consequently reduce the particle density in water in this study.

Limited studies showed that a diet of 50/50 mixture of algae and yeast supported growth comparable to a 100% algal ration when fed to the hard clam *Mercenaria mercenaria* (Epifanio 1979) and oyster *Crassostrea virginica* (Alatalo 1980). Although yeast could be used as algal substitutes for feeding bivalves, filtration rate or ingestion selectivity was not compared between yeast and algae in those studies. In our study, filtration rate and pseudofeces production were higher for yeast Y than for planktonic algae N and T grouped together. The higher filtration rate for Y could not be

TABLE 2.

Main effects of 6 diets, 2 clam sizes, their interactions and 5 orthogonal contrasts for diets on hard clam pseudofeces production.

SV	Mean	df	SS	MS	F	P > F

attributed to particle size, because particle size of Y (6 μm) was between T (8 μm) and N (4 μm). Nonetheless particles above 4 μm can be completely retained by *Mercenaria mercenaria* (Riisgård 1988). Higher pseudofeces production in Y for this hard clam might be attributed to yeast's lack of chlorophyll, because it was suggested that one of the two ways in which scallops could improve the quality of material ingested was through preferential rejection of nonchlorophyll-containing particles in the pseudofeces (Kiorboe & Møhlenberg 1981, Newell & Jordan 1983).

Filtration rates of clams fed on C were higher than when they were fed on F, Y and N, which were larger in particle size. This could be attributed to the hard clam's greater acceptance of C, which is possibly closer to a natural suspension comprising a mixture of various components than the other diets that contain only a single component. Previous studies demonstrated that addition of a small amount of mud to an algal suspension made the suspension closer to a natural one and only improved the clearance rate for *Mytilus edulis* (Kiorboe et al. 1980, Bayne et al. 1987) and *V. corrugatus* (Stenton-Dozey & Brown 1994).

Bivalves are traditionally regarded as suspension feeders for mainly phytoplankton and organic particles. In our study, pseudofeces production for F was no greater than S suggesting that for this clam preference for fishmeal, an animal-based substance, was no less than soybean meal, a plant-based substance. The higher filtration rate for S than for F could be attributed to its being 2 μm larger than the latter, or better quality.

Diet Concentrations

Our findings that filtration rate in *Meretrix lusoria* decreased with increasing concentration for all diets (Fig. 4) were in agreement with other literature studies for *Mytilus edulis*, *Cerastoderma edule* and *Venerupis pullastra*, filtering purely algal suspensions (Foster-Smith 1975); for *Mytilus edulis* feeding on resuspended fine mud (Widdows et al. 1979); for *Ostrea edulis* (Grant et al. 1990), for *Mya arenaria* (Grant & Thorpe 1991) and for *Cerastoderma edule* (Iglesias et al. 1992, Navarro & Widdows 1997), all feeding on mixtures of algal cells and suspended silt; and for *Ruditapes decussatus*, filtering suspended particulate matter (Sobral & Widdows 2000).

Bivalves can typically maintain a constant ingestion when ex-

Figure 4. Pseudofeces production of 2 size classes of hard clams receiving 6 diets (C; commercial hard clam feed, F; fishmeal, N; microalgae *Nannochloropsis oculata*, S; soybean meal, T; microalgae *Tetraselmis chui*, and Y; bread yeast). Averages not sharing any common alphabet (above data column) are significantly ($P \leq 0.05$) different.

posed to increasing seston concentrations by reducing clearance rate, increasing pseudofeces production or some combination of both mechanisms (Foster-Smith 1975, Winter 1978, Kiorboe et al. 1980, Bricelj & Malouf 1984, Bacon et al. 1998).

Filter-feeding activity is a function of cell concentration, which has been well documented by several authors for different species of lamellibranchiate bivalves (Sania 1976, Epifanio & Ewart 1977, Winter 1978). Similar reductions in clearance rates in response to increasing particle concentrations have been observed in epifaunal bivalves (Bayne et al. 1987) and infaunal bivalves including *Mercenaria mercenaria* (Bricelj & Malouf 1984). *Mya arenaria* significantly decreases its clearance rate in response to increasing particle concentration, showing about a 50% decline in rates, especially between 1 and 7 mg L⁻¹ (Bacon et al. 1998). In our study, although diet concentrations were much higher, ranging between 20 mg L⁻¹ and 633 mg L⁻¹, the decrease in filtration rate still held.

Clam Sizes

There have been few studies on body size effects on filtration rate in tropical marine bivalves, such as the species used in this study. Our results showed that weight-specific filtration rate declined with increase in body size (Fig. 1, Fig. 2). Instead of using weight-specific filtration rate, Riisgård (1988) demonstrated that the filtration rate (F , L h⁻¹) in *Mercenaria mercenaria*, *Crassostrea virginica* and *Geukensia demissa* increased with increasing dry weight of soft parts (W , g) according to the equation: $F = aW^b$. Such allometric relationship was well applied to several bivalves of which the filtration rates were measured by various methods (Gosling 2003). Nakamura (2001) also showed that the clearance rate for each category of chlorophyll *a*-containing particles (bacteria, picocyanobacteria, flagellates and *Nitzschia*) had a positive correlation with soft-body dry weight. In fact, there was no contradiction in results between those and ours, because weight-specific filtration rate or unit weight filtration rate (Epifanio & Ewart 1977) was inversely related to the weight of the animal. That the rates of physiological processes increase as power

relationships with increasing body size, but rates per unit body mass tend to decrease with increasing size (Yukihira et al. 1998) provided further explanation for the relationship between filtration rate or weight-specific filtration rate and weight. Disregarding diet type, diet concentration and size class the allometric relationship between filtration rate and weight in this study was $F = 6.95 W^{0.81}$.

Interaction

This study showed that the interactions between clam sizes, diets and diet concentrations had significant effects on filtration rate. It was obvious that the acceptance of various diets by small clams was different from that in large clams, if filtration rate was used as a measure of diet acceptance. Such interaction effects on filtration rate, to our surprise, were almost never reported. The only related study by Pérez-Camacho et al. (1994), indicated that the filtration rate of *Ruditapes decussatus* veliger larvae decreased with increasing diet concentration; however, the decrease in filtration rate was less pronounced in large than small clams. Such dissimilar responses for animals of different sizes were similar to those obtained in our study.

This study used filtration rate and pseudofeces production as response parameters to determine the ingestion preference of various sizes of hard clams for diets of various categories and concentrations. We first used DMRT to examine the feasibility of using particle size as an individual effect to explain ingestion preference across all 6 diets. Furthermore, we used orthogonal contrasts to compare systematically the ingestion preference for diets under various categories, such as shape regularity of diet particle (regular vs. irregular), chlorophyll content in live microbes (phytoplankton vs. yeast), complexity of diet composition (single component vs. multiple components) and plant-based diet versus fishmeal. The results suggested the complications in ingestion preference (Ward & Shumway 2004) require many more specific and detailed trials before a practical and realistic compound feed for the hard clam can be formulated.

GROWTH RATE AND LONGEVITY OF *DREISSENA POLYMORPHA* (PALLAS): A REVIEW AND RECOMMENDATIONS FOR FUTURE STUDY

ALEXANDER Y. KARATAYEV,^{1*} LYUBOV E. BURLAKOVA¹ AND DIANNA K. PADILLA^{2,3}

¹Department of Biology, Stephen F. Austin State University, Nacogdoches, Texas 75962; ²Department of Ecology and Evolution, Stony Brook University Stony Brook, New York 11794; ³National Center for Ecological Analysis and Synthesis, 735 State Street Suite 300, Santa Barbara, California 93101

ABSTRACT We review the variety of methods that have been used over the last 50 y in the Former Soviet Union, Eastern and Western Europe, and recently in North America to determine growth rate and longevity in zebra mussels (*Dreissena polymorpha* [Pallas]). These methods include: counting annual rings, analysis of size-frequency distributions, following growth under experimental conditions and monitoring marked mussels under natural conditions, without removing them from substrate. The last method provides the most reliable data, however this is the least common method used. *Dreissena polymorpha* growth rates depend on water temperature, season of the year, location in the water column, food availability, oxygen concentrations, water velocity and various other environmental factors. However, it is very difficult to separate the independent effects of each of these factors, especially in natural waterbodies. Several factors may overlap and have additive or synergistic effect that makes it difficult to determine the effects of a single factor. When comparing among studies that used the same methods, we found that zebra mussels grow faster in reservoirs than in lakes. The reported longevity of *D. polymorpha* varies from 2–19 y and it is not clear to what extent this variation is caused by biological variability and environmental conditions and what amount of the variation is caused by the methods used to assess age and longevity.

KEY WORDS: zebra mussels, *Dreissena polymorpha*, growth, growth rate, methods, longevity

INTRODUCTION

The zebra mussel, *Dreissena polymorpha* (Pallas), is one of the most pervasive invaders in freshwaters of the northern hemisphere. However, many aspects of the basic biology of *D. polymorpha* that are necessary for understanding and predicting the population dynamics and ecological impacts of this invader are still not well known. In addition, much of the research on the biology of *D. polymorpha* that has been conducted in the former Soviet Union (FSU), has not been published in English, and therefore it is not available to most scientists currently studying *D. polymorpha*. Growth rate and longevity are particularly important for understanding the population biology and ecological impacts of zebra mussels, especially because fecundity and filtering capacity increase with body size. Most of the published research has been conducted with the invasive subspecies *Dreissena polymorpha polymorpha*, which is capable of living in totally fresh water and has been the major invader in most places where dreissenids have been introduced. Less work has been conducted with *Dreissena bugensis* (Zhuravel 1951, MacIsaac 1994, Baldwin et al. 2002), *Dreissena polymorpha andrusovi* (Karpevich 1952, 1964, Lvova et al. 1983, 1994) and *Dreissena caspia* (Karpevich 1952, 1964).

Here we review the variety of methods used to estimate growth and longevity of zebra mussels over the last 50 y (Table 1, Table 2), discuss limitations of each and recommend the most appropriate methods for measuring growth and longevity in the field. We also synthesize the impacts of a range of environmental factors on growth and longevity in zebra mussels.

METHODS TO ESTIMATE GROWTH RATE

Rings on Shells

One of the oldest and most common methods for estimating the growth rate of zebra mussels is by counting annual rings on shells

of different sizes, and then calculating the average length of each age group of *Dreissena* in a population (Karpevich 1952, 1964, Kachanova 1963, Stanczykowska 1964, Lyakhov & Mikheev 1964, Mikheev 1964, Kornobis 1977, Karatayev & Tishchikov 1979, Kirpichenko & Antonov 1982, Dorgelo & Gorter 1984, Draulans & Wouters 1988, Miroshnichenko 1990). Plotting the average size of each age group against their age provides a growth rate curve. The advantage of this method is that by measuring individuals at a single point in time estimates of growth over several years can be made. However, counting growth rings is very subjective as it is difficult to distinguish annual rings from rings formed because of other factors that slow growth. Morton (1969a) found that two rings are formed annually: when growth slows during the winter and during spawning. Lvova (1980) found in the Uchinskoe Reservoir, 3–9 rings on the shells of 3-y-old mussels grown in cages for 2 y. In Czos Lake Lewandowski (1983) found from 1–3 rings on the shells of 1-y-old *D. polymorpha*, and from 2–5 rings on 2-y-old mussels.

Many other authors have also reported difficulties in distinguishing annual rings (Karpevich 1964, Kirpichenko 1965, Morton 1969a, Wiktor 1969, Lvova-Kachanova 1972, Lvova 1980, Lewandowski 1982a, Karatayev 1983, bij de Vaate 1991, Lvova et al. 1994). Often mussels with distinct rings can be found side by side with mussels without rings (Lvova 1980, Lvova et al. 1994, Jantz 1996). Moreover, 1-mm zebra mussels that settle at the end of the growing season do not produce a first annual ring. Therefore, these mussels would be incorrectly identified as young-of-the-year the following year.

Size-Frequency Distributions

Size-frequency distributions have been used in a number of studies of *D. polymorpha* growth rates (Morton 1969a, Jantz & Neumann 1992, Martel 1993, 1995, Smit et al. 1993, Dall & Hamburger 1996, Chase & Bailey 1999a, Orlova & Panov 2004), and can be useful if there is highly synchronized spawning and settlement and low interindividual variation in growth. Newly settled

Year-to-year variation	Growth varies significantly	Lvova 1980, Dorgelo 1993, Chase & Bailey 1999b

mussels form a distinct size class maintain distinct size structure for all age/size classes (Golikov 1970). However, in many water bodies *D. polymorpha* spawn throughout the entire summer, producing several peaks in veliger densities during the year (Lvova 1977, 1980, Karatayev 1983, Lvova et al. 1994, Burlakova 1998) and a wide size range (up to 16 mm difference in size) by the end of their first growing season (Wesenberg-Lund 1939, Mikheev 1964, Kirpichenko 1971, Szlauer 1974, Lvova 1977, Lewandowski 1983, Neumann et al. 1993, Martel 1995). Therefore, age classes will not form distinct size classes (Karatayev 1983, bij de Vaate 1991, Jantz & Neumann 1992, Lvova et al. 1994). This method is most effective when *D. polymorpha* spawn synchronously, have fast growth and are short lived, such as the shallow areas of the Svisloch River (Burlakova 1998). In this river *D. polymorpha* settle in the summer and grow during the following year, producing two distinct size classes of mussels (0+ and +) because the majority of older mussels die over winter because of fluctuating water levels and predation by ducks. At deeper depths mussels survive longer, producing many age classes, which are less distinct as cohorts, making this method less useful (Burlakova 1998). This method could also be used for studies that follow growth on experimental substrates when the time of settlement is known (Lvova 1977, Sprung 1992).

Growth Under Experimental Conditions

Many studies have been used to estimate *D. polymorpha* growth under experimental conditions, especially in cages. In the FSU this method was used in Kuyhyshevskoe (Mikheev 1964), Uchinskoe (Lvova-Kachanova 1972, Lvova 1980) and Tsimlyanskoe (Lvova et al. 1983) reservoirs, in Lake Lukomskoe (Karatayev 1983), the Narochansk lakes and the Svisloch River (Burlakova 1998). More recently, this method has been used by East European (Stanczykowska & Lewandowski 1995), West Eu-

ropean (Smit et al. 1992, 1993, Sprung 1992, 1995a, Dorgelo 1993, Dall & Hamburger 1996) and North American scientists (Bitterman et al. 1994, MacIsaac 1994, Allen et al. 1999, Horvath & Lamberti 1999, Yu & Culver 1999, Garton & Johnson 2000).

Other methods for studying mussel growth under experimental conditions include growing mussels on artificial substrates (Dorgelo & Gorter 1984, Sprung 1992, Martel 1993), and in the laboratory (Walz 1978a, 1978b, Jantz & Neumann 1992, 1998, Dorgelo 1993, Neumann et al. 1993, Jantz 1996, Baldwin et al. 2002). All of these methods could produce different types of artifacts, which may influence observed growth rates. Mesh, usually 3–5 mm, may prevent normal water flow through the cage, particularly for smaller mesh sizes (e.g., 1.2 mm, Garton & Johnson 2000). Cages can also be overgrown by periphyton, further reducing water flow (Kachanova 1963, Karatayev 1983, Stanczykowska & Lewandowski 1995, Burlakova 1998). However, the effects of caging artifacts on growth rates are usually not well tested or quantified (see Burlakova 1998 later).

Marked Mussels Under Natural Conditions

Following tagged mussels under natural conditions has been used in very few studies (e.g., Stoeckman & Garton 1997, Burlakova 1998) although this method could provide the most realistic estimates of zebra mussel growth rates. Burlakova (1998) found that the growth rate of mussels on stones in the Svisloch River was greater than that for caged mussels in the same environment (Fig. 1A). Early in the spring (April), when macrophytes and periphyton abundances were low, the difference between caged and uncaged mussels was small (~30%). This difference increased to almost 400% in the middle and especially by the end of the growing season when the quantity of drifting plants in the water increased and periphyton densities were high (Burlakova 1998). The disadvantage of this method is that zebra mussels can move, form

druses or be consumed by predators, making it difficult to follow individuals through time.

IMPACT OF ENVIRONMENTAL FACTORS ON GROWTH RATE

The growth rate of *Dreissena* depends on water temperature, season of the year, location in the water column, trophic conditions, which affect food availability, and water velocity as well as other environmental factors (Table 1).

Temperature

It is well established that the growth rate of *D. polymorpha* is accelerated by increased water temperature (Table 1). Especially convincing are data from studies in different temperature zones of cooling water reservoirs for thermal power plants in the FSU (Yaroshenko & Naberezhnyi 1971, Skalskaya 1976a, 1976b, Elagina et al. 1978, Karatayev & Tishchikov 1979, Karatayev 1983,

1984, 1988) and other areas of Eastern Europe (Stanczykowska 1976a, Kornobis 1977). In these studies *D. polymorpha* growth rates were compared among the various temperature zones of the same waterbody or lakes within same lake system. Therefore, environmental conditions other than temperature were similar, allowing a direct estimate of thermal effects.

However, when the maximum temperature is $>30^{\circ}\text{C}$, *D. polymorpha* growth decreases, and at temperatures $>32^{\circ}\text{C}$ most mussels die. In the hottest zone of Lukomskoe Lake, where maximum summer temperature exceeds 32°C , more than 90% of the *D. polymorpha* in experimental cages died, whereas in the moderately heated zone (maximum summer temperature $\leq 30^{\circ}\text{C}$) mortality was less than 10% and did not differ from the control, ambient zone (Karatayev 1983). Similar upper maximal temperature limits for *D. polymorpha* survival have been found by other authors in different regions of the FSU: 31.5°C in Zaporozhskoe Reservoir and 32°C in a canal of the Pridnieprovskaya Power Station in

Figure 1. A. Growth rate (mm/day) of caged (filled circles) and uncaged (open circles) *Dreissena polymorpha* in the Svisloch River in 1995 (from Burlakova 1998). Data points are the growth rates of individual mussels. Regression lines (uncaged – solid line, $Y = 0.129 - 0.005 \cdot X$, $R^2 = 0.78$, $P < 0.001$; caged – dashed line, $Y = 0.084 - 0.003 \cdot X$, $R^2 = 0.71$, $P < 0.001$) and 95% confidence intervals are shown. Uncaged mussels grew faster than caged mussels. The two regression lines differ significantly in slope ($P = 0.003$). B. Growth rate of caged and uncaged *D. polymorpha* in the Svisloch River with the regression lines for size-specific growth of *D. polymorpha* in cages in lakes (dashed line) and reservoirs (solid line). Caged mussels in the river grew at rates more similar to those caged in lakes, whereas uncaged mussels grew at rates more similar to those caged in reservoirs.

Ukraine (Lyakhovich et al. 1994), 32°C in Kuchurganskiy Liman in Moldova (Vladimirov 1983), 33°C in a cooling reservoir of the South-Ukrainian Nuclear Power Station (Sinitsina & Protasov 1993) and 34°C in a cooling reservoir of the Chernobyl Nuclear Power Station (Protasov et al. 1983).

The upper temperature limit for *D. polymorpha* in European cooling reservoirs is similar to that found in the Lower Mississippi River, where maximum temperature in the summer exceeds 30°C (Allen et al. 1999). In this river *D. polymorpha* growth rate is highest during spring and fall when temperatures ranged from 16°C to 28°C, however, shell growth ceases during the summer when temperatures remain 29°C to 31°C (Allen et al. 1999). Mihuc et al. (1999) found that in the Atchafalaya River system (Louisiana) *D. polymorpha* grow throughout the winter and growth in-

creases in late spring (April and May). Adult mortality occurs from May to August because dissolved oxygen levels decline and minimum daily temperatures warm above 29°C in the floodplain and 32.5°C in riverine sites. Thus, the maximum upper temperature limit for *D. polymorpha* survival is similar in both Europe and North America.

Season

In temperate regions, zebra mussel growth stops in the winter and resumes in the spring after water temperatures warm. Although Smit et al. (1992) assumed that the lower temperature limit for shell growth should be set by the lower temperature limit for filtering (3°C; Mikheev 1967a, 1967b, Kondratiev 1969, Reeders & bij de Vaate 1990), a majority of studies have found that the threshold temperature for mussel growth is 10°C to 12°C (12°C, Kachanova 1961; 11°C, Morton 1969a, 1969b; 10°C, Alimov 1974, Karatayev 1983, Jantz & Neumann 1992; 10°C to 12°C, Mackie 1991). bij de Vaate (1991) did report a lower temperature limit of 6°C, however in North America MacIsaac (1994) found that small mussels incubated at 6°C experienced shell degrowth and mass loss, whereas large individuals experienced shell degrowth but weight gain. These differences among studies may be the result of local effects, but clearly call for further study.

Maximum growth in *D. polymorpha* is usually found early in the growing season (Karatayev 1983, 1984, Smit et al. 1992, Lvova et al. 1994, Burlakova 1998, Garton & Johnson 2000), and corresponds with a peak in phytoplankton abundance (Walz 1978a). In midsummer growth rate often decreases (Spiridonov 1971, Walz 1978a, Smit et al. 1992, Stanczykowska & Lewandowski 1995, Allen et al. 1999) and has been attributed to low food concentrations (Walz 1978a), blooms of dinoflagellates (e.g., *Ceratium hirundinella*) that impede filter feeding (Stanczykowska & Lewandowski 1995), high water temperatures (Allen et al. 1999) and spawning (Spiridonov 1971, Lvova 1977, 1980, Karatayev 1983, 1992, Allen et al. 1999). In the autumn, when water temperatures decrease, growth stops (Morton 1969a). In the Uchinskoe Reservoir growth stops when temperatures fall to 10°C (Lvova 1977, 1980) and in the River Rhine at 10° to 15°C (Jantz & Neumann 1992).

Based on a bioenergetics model of zebra mussel growth in the Laurentian Great Lakes, Schneider (1992) predicted positive growth in the spring and fall when high phytoplankton biomass associated with spring and fall turnover coincides with temperatures near the optimum for growth. Even under conditions of high food availability, growth rates in his model typically decline in the beginning of summer and increase again in August and September as temperature begins to decline. Schneider (1992) used Walz's bioenergetic estimates of metabolic parameters for zebra mussels from Lake Constance (Walz 1978d), where the optimal temperature range for growth is 8°C to 15°C. This temperature range is much lower than optimum found by other authors, and therefore more empirical tests of this model are needed before we can assess the generalizability of its predictions.

Location in the Water Column

Dreissena polymorpha grow faster in the water column above the bottom (e.g., on buoys, cages, submerged constructions, floating objects) than on the bottom (Kachanova 1963, Mikheev 1964, bij de Vaate 1991, Smit et al. 1992, 1993, Dorgelo 1993, Burlakova 1998). Yu and Culver (1999) tested the effect of cage loca-

tion in stratified Hargus Lake (Ohio), and found highest growth at their pelagic site (2.5–4 m depth) and in the littoral zone at 2.5 m depth. All mussels held below the thermocline (5-m depth) died before the end of experiment (163 days).

Trophic Conditions

Trophic conditions also affect zebra mussel growth (Table 1). Dorgelo (1993) found that zebra mussels growth rates in Dutch eutrophic lakes Mararsseveen II and Vechten was higher ($0.54\text{--}0.59\text{ mm wk}^{-1}$) than of those grown in mesooligotrophic Lake Maarsseveen I (0.35 mm wk^{-1}), even though there was no difference in mean temperature between these lakes. Jantz and Neumann (1992) found a significant strong correlation ($r_s = 0.80$) between the rate of shell length growth and chlorophyll *a* concentration and between shell growth and temperature ($r_s = 0.82$). However, because these two environmental factors are highly correlated, it is impossible to determine the relative contribution of each of these factors on growth (Jantz & Neumann 1992). In a later study (Jantz & Neumann 1998) they found that shell growth rate and the duration of the growing season were correlated with the quantity of available algal food.

Sprung (1995a) found a strong correlation between zebra mussel shell growth and food conditions (siston concentration). He suggested that this correlation will exist when siston concentrations stay below those at which the intestine is filled to capacity when the animal filters at a maximum rate (Sprung 1995b). Similarly, Schneider et al. (1998) found that the scope for growth under laboratory conditions had a strong positive relationship with food quality.

Water Motion

In areas with constant water current *D. polymorpha* grow faster than in still water (Table 1). Kachanova (1963) found that *D. polymorpha* grow faster on the concrete walls of the canal flowing from Uchinskoe Reservoir than in the reservoir. Mikheev (1964) found that in Kuybyshevskoe Reservoir moderate water currents (up to 0.8 m s^{-1}) facilitate mussel feeding and respiration and *D. polymorpha* grown in water currents reached 27–28 mm, whereas same aged mussels at the same depth out of currents were only 19–20 mm in length. Smit et al. (1993) suggested that water movement seems to have a larger influence on growth than the amount of algal food in the water column. They found that the young-of-the-year zebra mussels in the Rhine River were almost 3 times longer (16 mm) than in Lake IJsselmeer (6 mm) in spite of lower chlorophyll *a* concentrations in the river ($10\text{--}42\text{ }\mu\text{g L}^{-1}$ in the river, $34\text{--}106\text{ }\mu\text{g L}^{-1}$ in lakes).

However, strong water currents may inhibit *Dreissena* growth. The maximum length of 2-y-old zebra mussels in waterways of the Kuybyshevskaya hydroelectric power plant with constant water currents $<0.5\text{ m s}^{-1}$ was 18 mm, and in places with water currents $>1.5\text{ m s}^{-1}$ was 13–14 mm (Mikheev 1964).

Wave action can also inhibit *D. polymorpha* growth. Mikheev (1964) found that in the littoral zone of Kuybyshevskoe Reservoir exposed to waves, the average (4–5 mm) and maximum (8–10 mm) length of yearling mussels was almost half that of mussels at the same depth but without waves (7.2 mm mean, 14 mm maximum). He also found that the average length of the young-of-the-year *D. polymorpha* in parts of the Tsimlyanskoe Reservoir exposed to strong waves was 9 mm (maximum 12.5 mm), whereas in

quiet areas at the same depth the average length was 12 mm (maximum 19.2 mm).

Depth

Dreissena polymorpha grow faster in shallow than in the deep parts of a waterbody (Table 1). In Kuybyshevskoe Reservoir the maximum length of yearling mussels at 1–1.5 m depth was 13.7–14 mm, and at 20 m depth, only 6–7 mm (Mikheev 1964). Similarly, Garton and Johnson (2000) found that in Lake Wawasee zebra mussel growth rate declined 15% per meter between 1–4 m depth. They hypothesized that this decrease was caused by lower temperature and reduced food with depth.

Turbidity

High concentrations of suspended matter in the water negatively affects filtration, ingestion, assimilation and growth potential of zebra mussels (Reeders et al. 1989, Noordhuis et al. 1992, Alexander et al. 1994, Summers et al. 1996, Madon et al. 1998, Schneider et al. 1998). In Dutch lakes, clearance rates of adult 20-mm zebra mussels declined exponentially as dry suspended matter increased from $5\text{--}90\text{ mg L}^{-1}$ (Reeders et al. 1989, Noordhuis et al. 1992).

Madon et al. (1998) found that concentrations of suspended inorganic sediment above 1 mg L^{-1} , and a ratio of inorganic to organic fraction of seston higher than 1.71 may cause negative growth. Similar limits were found by Schneider et al. (1998); the scope for growth declined with decreasing food quality and fell below $0\text{ cal mg}^{-1}\text{ h}^{-1}$ at an organic/inorganic ratio of 0.5. They suggested that high concentrations of suspended inorganic sediment in large turbid rivers represents a difficult growth environment for zebra mussels and that populations in turbid rivers may not stabilize at the very high densities typical of lentic environments.

Year-to-year Variation

The growth rates of *D. polymorpha* in the same waterbody vary significant among years (Lvova 1980, Dorgelo 1993, Chase & Bailey 1999b). Zebra mussels in the Uchinskoe Reservoir with initial shell lengths of 8 mm grew to $21.2 \pm 0.29\text{ mm}$ by the end of the growing season in 1967, to $19.5 \pm 0.27\text{ mm}$ in 1968, and to $16.8 \pm 0.18\text{ mm}$ in 1969 (Lvova 1980). Dorgelo (1993) found the growth rate of *D. polymorpha* in lakes Maarsseveen I and II was significantly lower in the summer of 1986 than in 1985. In a study of growth and production of *D. polymorpha* in lakes St. Clair, Erie and Ontario, Chase and Bailey (1999b) estimated shell production as a part of total production (total production = shell + somatic + gamete production). They found that the site by year interaction (among 5 populations) explained $>80\%$ of the variation; differences between sites in production depended on the year examined. Variation in total production depended on variation in somatic and shell production only, as gamete production was relatively constant among years. Chase and Bailey (1999b) hypothesized that, in response to poor environmental conditions, *D. polymorpha* shifts the allocation of resources from growth (somatic and shell) to reproduction. As individuals cannot predict how long adverse conditions will persist, investment in growth may be unprofitable (Chase & Bailey 1999b).

Lakes versus Reservoirs

Although environmental factors that affect mussel growth such as temperature, food availability and other conditions can differ

greatly among waterbodies and among years within the same waterbody, when we compared size-specific growth rates of zebra mussels among studies that all used a similar method (following caged mussels), some patterns emerged. We compared the data for size specific zebra mussel growth from three studies in reservoirs (two different reservoirs, two different years in one reservoir) and six studies conducted in 5 different lakes (4 in Eastern Europe, 1 in North America). We found that the size-specific growth of mussels in reservoirs was consistently higher than that of mussels grown in lakes (Fig. 2). Surprisingly, given the range of likely conditions among water bodies and among years, growth in reservoirs was very consistent ($R^2 = 0.92$). For lakes there was more spread ($R^2 = 0.72$), but the patterns and rates were similar among studies. Data for the growth of uncaged mussels in the Svisloch River are much more similar to mussels in reservoirs, whereas those grown in cages were more similar to mussels in lakes (Fig. 1 B).

LIFE SPAN

Methods to Estimate Longevity

Most of the methods used to estimate longevity of *D. polymorpha* are similar to those used to estimate growth rate: counting annual rings on shells, analysis of the size-frequency distributions and growth under experimental conditions (Table 2).

Counting Annual Rings on Shell

The maximum longevity reported using this method has decreased through time from 17–19 y (Karpevich 1964) to 4–5 y

(Draulans & Wouters 1988). Through time some authors have revised their earlier estimates of zebra mussel longevity. Stanczykowska (1964) initially reported a maximum longevity for *D. polymorpha* of 10–12 y; 11 y later she revised her estimates from these same data to 5 y (Stanczykowska 1975, 1976b). Kachanova (1963) (this author published later under the name Lvova-Kachanova and Lvova) reported that the maximum life span of zebra mussels in the Uchinskoe Reservoir was 6–11 y, and later revised this estimate to 4 y (Lvova 1980, Table 2). Although the advantage of this method is that it allows an estimate of the age structure of a population by measuring *D. polymorpha* at a single point in time, as discussed earlier, it is very difficult to separate annual rings formed during winter from other rings.

Analysis of Size-frequency Distributions

For this method the numbers of peaks on a size-frequency histogram are counted, assuming that each peak represents an age class. However, as discussed earlier, age classes may not have distinct sizes, making it difficult to estimate longevity based on size-frequency distributions.

Growth Under Experimental Conditions

Usually authors keep mussels of different initial sizes in cages for a limited period (1–4 y), and then the obtained growth rates are used to estimate the time to reach the maximum size found in the population. However keeping mussels in cages can produce different types of artifacts discussed earlier, which may affect observed growth rates and, therefore, estimates of mussel longevity.

Factors Affecting Longevity

To our knowledge, the first estimates of the longevity of zebra mussels were reported by Karpevich (1952) and Clarke (1952) (Table 2). Karpevich (1952) counted annual rings on shells and estimated zebra mussel longevity in the Volga River as 18 y. In contrast, Clarke (1952) using unpublished data from J. Wilhelm (study site not mentioned) found three peaks in the size-frequency distribution of *D. polymorpha* and suggested that typical longevity is about three years. Overall, the longevity of *D. polymorpha* estimated by different authors over the last 50 y varies from 2–19 y. However, the maximum sizes of *D. polymorpha* reported by these authors are similar (Table 2). This contradiction supports a hypothesis that the reported differences in longevity may be explained to a large extent by the artifacts of the methods used. This suggestion is also supported by the fact that the average *D. polymorpha* longevity estimated by counting annual rings on shells (7.4 ± 0.9) is significantly different from average longevity estimated by analysis of size-frequency distribution (3.3 ± 0.3 , $P < 0.001$, 2-sided *t*-test) (Table 2). Alternatively, zebra mussels may have a fixed maximum size, and local conditions that affect growth rates determine longevity—fast growing mussels will live for shorter periods of time, whereas slow growing mussels will live longer. Therefore, it is unclear how much of this variability in longevity is natural or is caused by the artifacts of the methods used and definitely requires future investigation.

GENERAL FINDINGS AND FUTURE DIRECTIONS

Although many generalizations can be made about the growth rate and longevity of *D. polymorpha*, and the impacts of various environmental factors on these parameters, the answers to many questions are far from clear. The most important questions that

Figure 2. Growth rates of *Dreissena polymorpha* in reservoirs (filled symbols) and lakes (open symbols, stars and crosses). In all studies, zebra mussels were kept in cages and followed through time. Regression lines are for size-specific growth rate in reservoirs (solid line, $Y = 0.102 - 0.003X$, $R^2 = 0.92$, $P < 0.001$) and lakes (dashed line, $Y = 0.053 - 0.002X$, $R^2 = 0.72$, $P < 0.001$) with 95% confidence intervals. The two regression lines significantly differ in slope ($P = 0.013$) and their 95% confidence intervals do not overlap. Data sources are: ● Uchinskoe Reservoir, 1967 and ▲ Uchinskoe Reservoir, 1968 (Russia)—Lvova (1980), ■ Tsimlyanskoe Reservoir (Russia)—Mirshnichenko (1990), ○ Lake Lukomskoe, unheated zone and □ Lake Lukomskoe, heated zone (Belarus)—Karatayev (1983), △ Mikolajskie Lake (Poland)—Stanczykowska & Lewandowski (1995), ○ Lake Naroch (Belarus)—Burlakova (1998) and + Lake Myastro (Belarus)—Burlakova (1998), * Lake Wawasee (US)—Garton & Johnson (2000).

need to be addressed, problems that need to be solved, and targets for future study are:

Methodological Problems

Growth rate and longevity of *D. polymorpha* have been estimated by using four different methods, most of which have serious methodological problems. Thus, different estimates of *D. polymorpha* growth rates and longevity are affected not only by differences in environmental conditions but also by artifacts of the methods used. Following the growth of undisturbed *D. polymorpha* will provide more reliable data on growth potential and variability among different waterbodies with different environmental conditions. Following and subsampling mussels that naturally settle on experimental surfaces through time provides the control and ease found in experimental studies with the growth rates expected from natural populations.

Co-effects of Environmental Factors

Dreissena polymorpha growth rates depend on water temperature, season of the year, location in the water column, food availability, oxygen concentrations, water velocity and various other environmental factors (Table 1). However, it is difficult to separate the independent effects of each of these factors, especially in natural waterbodies where most of these factors will covary. Several factors may have additive or synergistic effects, making it difficult to study the effect of a single factor. Separation of the effects of single and combined factors on growth is essential.

Temperature

The upper temperature limit for zebra mussel growth seems to be 30°C to 32°C, and the lower temperature limit ~10°C to 12°C (Kachanova 1961, Morton 1969a, 1969b, Alimov 1974, Karatayev, 1983, Mackie 1991, Jantz & Neumann 1992). However, some studies have found much lower limits (bij de Vaate

1991, Smit et al. 1992). Differences among studies may be a result of local effects but clearly calls for further study.

Growth in Different Types of Waterbodies

There seems to be substantial differences in growth between mussels in reservoirs and lakes—mussels grow much faster in reservoirs than lakes. Experiments that directly test the relative contributions of environmental factors versus the type of water body and what factors are different between reservoirs and lakes are clearly called for to answer this question. It may be that reservoirs provide a better overall growth environment in terms of temperature, nutrition, and water motion than do natural lakes or rivers.

Longevity

The reported longevity of *D. polymorpha* varies from 2 to 19 y. It is critically important to understand to what extent this variation is caused by biological variability, environmental conditions and what amount of the variation is caused by the methods used. In addition to the basic value of understanding the variability in *D. polymorpha* longevity, it is also important if we are to predict population dynamics, spread or to develop control methods for this important invader.

ACKNOWLEDGMENTS

The authors acknowledge the support provided by Stephen F. Austin State University (Faculty Research Grant # 14123 to AYK, LEB and DKP, 2003 to 2004). In the Republic of Belarus the research was supported by a grant from the Ministry of Education and Science Republic of Belarus, grant number 657/65. This work was conducted while D. Padilla was a Sabbatical Fellow at the National Center for Ecological Analysis and Synthesis, a center funded by NSF (Grant #DEB-0072909), the University of California and the Santa Barbara campus.

POPULATION STRUCTURE IN TWO MARINE INVERTEBRATE SPECIES (*PANOPEA ABRUPTA* AND *STRONGYLOCENTROTUS FRANCISCANUS*) TARGETED FOR AQUACULTURE AND ENHANCEMENT IN BRITISH COLUMBIA

KRISTINA M. MILLER,* K. JANINE SUPERNALUT, SHAORONG LI AND RUTH E. WITHLER

Fisheries and Oceans Canada Pacific Biological Station, 3190 Hammond Bay Rd. Nanaimo, BC Canada V9T 6N7

ABSTRACT As the number of native species targeted for aquaculture and enhancement in British Columbia (BC) rises, fisheries managers must develop policies and species-specific management plans that facilitate industry expansion while protecting the integrity and fitness of wild stocks. Whereas genetic introgression of domesticated stocks with wild stocks cannot be completely eliminated, some control can be gained by limiting the collection and culture of domesticated stocks to geographic units defined by the genetic structure of wild stocks. We describe the genetic structure of two species that are targeted for intensive enhancement and aquaculture in BC: Geoduck clams, *Panopea abrupta* and red sea urchins, *Strongylocentrotus franciscanus*. Based on a survey of eight polymorphic microsatellite loci, *P. abrupta* contained significant geographic structure within BC, with the distribution of genetic variation consistent with stepping stone gene flow under an isolation-by-distance model. A survey of seven polymorphic microsatellite loci covering a similar geographic range revealed genetic homogeneity of *S. franciscanus* in BC. Based on the different levels of structure displayed in the two species, we propose three geographically-based management units for *P. abrupta* and two for *S. franciscanus* in BC.

KEY WORDS: geoduck, clam, red sea urchin, *Panopea abrupta*, *Strongylocentrotus franciscanus*, population structure, enhancement, genetic, microsatellite

INTRODUCTION

In British Columbia (BC), many native (mussels) and nonnative (oysters, manila clams, Japanese scallops, Atlantic salmon) marine species are under intensive aquaculture. Additional species that are important capture fisheries are also becoming prospects for aquaculture and artificial enhancement (e.g., geoduck, urchins, blackcod, halibut and rockfish species). Different genetic issues accompany the widespread hatchery production of native and nonnative species. In the culture of nonnative species, competition and hybridization with native species are potential impacts, whereas in the culture of native species, reduction of the genetic fitness of wild populations through introgression with aquaculture strains is a primary concern (Utter & Epifanio 2002). There are three ways in which hatchery-reared animals may differ genetically from their wild counterparts. They may have a geographically distant origin and may be adapted to different natural conditions. Such organisms released from the hatchery may be relatively unfit in their new environment and hybridization with wild conspecifics may lead to outbreeding depression, a reduction in fitness of hybrids in the wild (Allendorf & Ryman 1987). When local organisms are used for hatchery propagation, the reduced number of parents successfully contributing to hatchery offspring can lead to founder effects, genetic drift and future inbreeding (Tave 1993). Even when large numbers of broodstock are collected locally, domestication, or adaptation to hatchery culture, may reduce the fitness of hatchery-produced organisms and their hybrids in the wild (Lynch & O'Hely 2001, Ford 2002).

Few species have been subjected to the detailed studies required to detect and quantify fitness differences between wild, cultured and hybrid organisms in the wild environment. For Atlantic salmon, one of the most intensively cultured and studied species worldwide, domesticated fish and their first-generation hybrids with wild fish have lower fitness than wild fish in natural

environments (McGinnity et al. 1997, Fleming et al. 2000, McGinnity et al. 2003). For invertebrate species, hatchery-produced organisms often contain reduced genetic variability compared with their wild conspecifics (Hedgecock et al. 1992, Boudry et al. 2002), but few studies have investigated the fitness of cultured individuals in different environments (see Tremblay et al. 2001, Jorstad et al. 2005, Sekino et al. 2005).

Because most cultured marine invertebrate species have pelagic larval dispersal stages, complete isolation of wild and hatchery-reared conspecifics could only be achieved by limiting culture to expensive on-land facilities, rearing of nonreproductive animals (e.g., triploids) or complete harvesting of cultured animals before they become reproductively mature. However, introgression of geographically distinct cultured stocks can be avoided by managing broodstock collection and outplanting within regions identified on the basis of wild population structure. Loss of variation and domestication in hatchery strains can be reduced by maintaining large broodstock numbers of wild origin organisms for hatchery production. Alternately, in the case where hatchery broodstocks are genetically distinct from wild stocks, either having undergone extensive genetic selection, bottlenecks or genetic marking, prior knowledge of the genetic characteristics of the wild populations and local hatchery broodstocks may enable monitoring in the vicinity of aquaculture sites and beyond to detect genetic interactions.

Most marine invertebrate species currently cultured or enhanced are characterized by high levels of fecundity and planktotrophic larvae with high dispersal capabilities, both features that are associated with genetic panmixia (Bohonak 1999). However, although panmixia is often observed in marine invertebrate species with these life history attributes, many species do not display panmixia over all spatial scales (Hellberg et al. 2002). The three additional types of structure most often observed include chaotic genetic patchiness, isolation by distance (IBD) and abrupt phylogenetic breaks associated with geographic barriers (reviewed in Hellberg et al. 2002). Chaotic genetic patchiness, defined by non-

*Corresponding author. E-mail: millerk@pac.dfo-mpo.gc.ca

geographically based genetic variance over space and/or time, has been observed over small to medium geographic scales (0–500 km) in a large range of marine invertebrate species (Johnson & Black 1982, Benzie & Williams 1997, Michinina & Rebordinos 1997, Moberg & Burton 2000, Hamm & Burton 2000). An IBD model of structure results from stepping stone gene flow (Slatkin 1993), and has been observed over macrogeographic (100s to 1,000s of km) scales in some marine invertebrate species (Shaklee & Bentzen 1998, Hellberg et al. 2002, Palumbi 2002). Alternately, abrupt genetic boundaries have been observed most often in species occupying bays and estuaries, or those crossing strong phylogeographic boundaries limited by ocean current circulation (Reeb & Avise 1990, Hellberg et al. 2002).

Geoduck clams, *Panopea abrupta* (hereafter *Pab*) and red sea urchins, *Strongylocentrotus franciscanus* (hereafter *Sfr*) are both long lived (up to 100–150 y) mainly dioecious species that form dense aggregations in the wild (Bureau et al. 2002, Ebert & Southon 2003). Larval duration (approximately 6 wk) is similar in both species, and repeat broadcast spawning events synchronized among individuals clustered over small spatial scales occur from spring through summer (Ebert et al. 1994, Goodwin & Bradbury 2001, Flowers et al. 2002). Because recruitment is sporadic, natural replenishment of over-fished sites is slow, with an estimated 30–50 y natural recovery time to preharvest levels for geoduck clams (Goodwin & Bradbury 2001). Enhancement with hatchery-reared juveniles to facilitate rebuilding has been in effect for intertidal geoduck clams in Washington State since 1982 and for

subtidal geoduck clams in BC (limited to the Strait of Georgia) since 1993 (http://www-sci.pac.dfo-mpo.gc.ca/geoduck/intro_e.htm). Recent experimental work on outplanting methods on red sea urchins has also been undertaken (Alan Campbell, pers. comm.).

Little is known about the genetic structure of *Pab* and *Sfr* in BC, although some genetic information exists on these species from other geographic locations, and genetic data is available on species closely related to *Sfr*. In this study we examine the genetic structure of geoduck clams and red sea urchins in BC with highly variable microsatellite loci (Kaukinen et al. 2004, Miller et al. 2004) and use the information to provide genetic guidelines for culture activities.

METHODS

Pab siphon tissue was collected from 16 sites ranging from Washington through northern BC and spanning over 1100 km of coastline (Fig. 1). Collections took place over a 3-y period, from 2000–2003. Ethanol preserved siphon tissue was extracted using the chelex method from Small et al. (1998). Variation at 2 dinucleotide (*Pab* 5, *Pab* 132) and 6 tetranucleotide (*Pab* 6, *Pab* 117, *Pab* 101e, *Pab* 105e, *Pab* 106e, *Pab* 112e) microsatellite loci isolated from *Pab* was surveyed using the primers and protocols outlined in Kaukinen et al. 2004 (note *Pab* 5 and 6 are from Vadopalas & Bentzen 2000).

Sfr were collected over 3 years from 13 sites spanning over

Figure 1. Map showing locations of *P. abrupta* and *S. franciscanus* collection sites in Washington, BC and Alaska. Collections were made for each species spanning a 3-y period, from 2000–2003.

1,000 km of coastline ranging from southern BC to Southern Alaska (Fig. 1 and Table 1). For *Sfr*, gonad tissue was collected destructively and frozen at -80°C until use. Genomic DNA was extracted using DNeasy kits (Qiagen, Valencia, CA). Variation at six polymorphic dinucleotide (*Sfr* 06, *Sfr* 13, *Sfr* 22, *Sfr* 34, *Sfr* 64 and *Sfr* 90) loci and one trinucleotide (*Sfr* 55) repeat microsatellite locus isolated from *Sfr* was surveyed using the primers and protocols outlined in Miller et al. (2004).

Allelic and genotypic frequency data were analyzed using the Genetic Data Analysis (GDA) (Lewis & Zaykin 2001), GENEPOP version 3.1d (Raymond & Rousset 1995) and FSTAT version 2.9.3.2 (Goudet 2001). Conformance to Hardy Weinberg equilibrium (HWE) distributions of genotypic frequencies at each locus in each sample was tested using GENEPOP. Levels of differentiation among populations using F_{ST} values (Weir & Cockerham 1984) were computed over all samples and on a pairwise basis between samples using FSTAT. For loci that were not in HWE, F_{ST} distances were calculated by randomized genotypes rather than alleles (Goudet 2001). The significance of the multilocus F_{ST} value over all samples was determined by jackknifing over loci. Allelic richness was calculated by standardizing allelic diversity to a sample size of 50 individuals in FSTAT. Homogeneity of allele richness and heterozygosity among sites was tested using a chi-square (χ^2) test. An IBD model of structure was tested by regression of pairwise F_{ST} values with geographic distance (shortest waterway distances between sites), calculated in FSTAT following Mantel (1967). The stability of the IBD model structure was tested using the web-based IBD program from <http://www.bio.sdsu.edu/pub/andy/BohonakCV.html#Computer%Programs>, with all values set to default (Bohonak 2002).

Genetic relationships among samples of *Sfr* and of *Pab* were determined using a dendrogram based on the neighbor-joining algorithm, constructed using pairwise differences (Nei 1978). The effective population size (N_E), which is an estimate of the number of breeding adults in a population, for *Sfr* and *Pab* was calculated from expected heterozygosity (H_E) values over all loci using the relationship $N_E = (1/[1-H_E]^2 - 1)/8\mu$, where μ is the mutation rate for the microsatellite loci (Lehmann et al. 1998). The mammalian mutation rate of $\mu = 10^{-4}$ was used as a conservative estimate, recognizing that N_E values could be 100 times greater if μ approaches 10^{-6} , as observed in *Drosophila* (Shug et al. 1997).

Hierarchical analysis of allele frequency variation was conducted in Arlequin with a nested analysis of molecular variance (AMOVA; random effects model; Weir 1996). The significance of allele frequency differences attributable to geographic regions identified in the dendrograms based on F_{ST} distances was tested in a hierarchical model with sample sites nested within regions.

RESULTS

Genetic Variation Within Samples

Pab microsatellite loci were all highly polymorphic. Allelic richness ranged from 16–38 alleles per 50 individuals, and expected heterozygosities ranged from 0.91–0.98 among loci (Table 2). Four of the eight *Pab* loci contained excess homozygotes resulting in significant deviations from HWE over all sites, whereas *Pab* 112e contained an excess at 11/16 sites (overall $P < 0.001$ for each of these loci). Deviations from HWE were minimal in the remaining three loci ($P > 0.1$ over all sites). Estimates of the inbreeding coefficient, F_{IS} , over all sites ranged from 0.03 for *Pab* 6 to 0.30 for *Pab* 117 (Table 2).

Abbreviations include: Washington (WA), BC (BC), Alaska (AK), East coast of Vancouver Island (ECVI), north ECVI (N-ECVI), west coast of Vancouver Island (WCVI), Queen Charlotte Islands (QCI), central coast (CC), and south east Alaska (SEAK). Allele frequencies for all samples surveyed in this study are available at: http://www.pac.dfo-mpo.gc.ca/sci/aqua/bgsid_e.htm.

Sfr microsatellite loci were slightly less polymorphic than *Pab* loci, with a range in allelic richness of 9–35 (mean 20) and a range in expected heterozygosity of 0.63–0.96. Fewer deviations from HWE were observed in *Sfr* than for *Pab*, with only two of the seven loci containing significant excesses of homozygotes in over 50% of the *Sfr* sites. As a result, the mean F_{IS} over all loci was lower in *Sfr* (0.11 ± 0.03) than in *Pab* (0.15 ± 0.04).

Using the mammalian microsatellite mutation rate (10^{-4}) and H_E values estimated from the loci in this study, locus-specific estimates of effective population sizes (N_E) for *Pab* ranged from 1.4–13.8 million (mean of 5.8 million), and for *Sfr* ranged from 0.08–9.7 million (mean of 2.1 million).

Genetic Variation Among Samples

In *Pab*, levels of heterozygosity were homogeneously distributed among sites ($P > 0.05$), whereas spatial heterogeneity in al-

TABLE 2.

Statistics on *S. franciscanus* and *P. abrupta* microsatellite loci, including allelic richness (A_R), expected (H_e), and observed (H_o) heterozygosity, inbreeding coefficient (F_{IS}), number of populations that deviate significantly ($P < 0.05$) from HWE after bonferroni correction, Coancestry coefficient (F_{ST}), and the associated P -value for F_{ST} . HWE was not assumed in the calculation of the Coancestry coefficient (F_{ST}) when 20% or more of the populations significantly deviated from HWE (highlighted with an asterisk).

¹ Locus primers from Vadopalas & Bentzen (2000).

allelic richness was observed ($P < 0.01$), with a greater number of alleles observed in southern sites (Table 1). Alternately, no significant heterogeneity in allelic richness or heterozygosity was observed among sites for *Sfr* ($P > 0.05$). Similarly, less variation in F_{IS} was observed among sites than among loci for both species (F_{IS} among sites: 0.12–0.13 *Pab*, 0.08–0.13 *Sfr*; F_{IS} among loci 0.05–0.30 *Pab*, 0.03–0.23 *Sfr*). Despite the high degree of polymorphism displayed at all loci of both species, few private alleles (i.e., alleles observed in only one site) were observed. Out of 355 alleles for *Pab* observed over all loci, only 6 were private. For *Sfr*, 24 of the 265 alleles were private. Private alleles were not found in either species at frequencies above 0.03, nor were they found disproportionately in specific sites or regions.

For both species, F_{ST} calculated over all loci and all populations was significantly greater than zero ($P < 0.01$); however, only the *Pab* F_{ST} was significant after jackknifing ($P < 0.0004$). The global F_{ST} estimate for *Pab* (0.004 ± 0.001) was twice as high as that observed for *Sfr* (0.002 ± 0.001). F_{ST} values for single *Pab* loci ranged from 0.002–0.005, and were significantly greater than 0 for all eight loci ($P < 0.05$) (Table 2). Alternately, for *Sfr*, F_{ST} values for single loci ranged from –0.001–0.006, and four of the seven loci (*Sfr* 34, 55, 64 and 90) were significantly greater than 0. When calculated on a pairwise basis, after bonferroni correction, over 85% of population comparisons were significant for *Pab*, versus only 10% for *Sfr* (Table 3).

The majority of the genetic variation in *Pab* was found within sites (99.5%), with only 0.4% partitioned among sites and 0.08% among regions. Sites represented a significant portion of the variation in the AMOVA (F-ratio = 1.88, df 12,16482, $P = 0.03$), but permutations of models based on different regional configurations did not reveal any significant effects of region ($P > 0.2$ in all models). However, in the neighbor-joining dendrogram, geoduck

samples generally clustered into four geographically-based units (Fig. 2A), and the mean F_{ST} values calculated among the four depicted regions (range of 0.003–0.005) were generally twice as high as those observed within regions (range of 0.002–0.003). The geographic cluster containing the three Queen Charlotte Island (QCI) samples, Gowgaia Bay, Hippa Island, and Tasu Sound, was the most distinctive. Although the two Washington samples, Point Heyer and Hood Canal, clustered together, they were fairly distinct from one another (significantly different at 3/8 loci), and were not highly differentiated from two of the East Coast of Vancouver Island (ECVI) sites, Marina Island and North Savory. However, they were well differentiated from all other sites on the BC coast. The remainder of the ECVI samples clustered together. The West Coast of Vancouver Island (WCVI) sites and single North Coast of Vancouver Island (NCVI) site formed the fourth cluster. In all, the distribution of genetic variation in *Pab* was consistent with an IBD model of structure ($R^2 = 25.5$, $P < 0.0001$; FSTAT), but it was clear from the low R^2 value that all sources of variation were not accounted for by this model (Fig. 3A). An IBD model of structure was also supported using the IBD program of Bohonak (2002), but the R^2 and P values were generally lower. A higher degree of significance was obtained when log values of genetic distance were used, and when the two Washington sites were removed ($P < 0.002$ versus $P < 0.023$). Alternately, IBD structure was not supported when the three QCI sites were removed ($P > 0.35$).

Despite the fact that a lower percentage of population pairs were significantly different in *Sfr* versus *Pab*, hierarchical gene diversity analysis revealed a slightly greater amount of variation partitioned among sites than observed in *Pab* (1.24% vs. 0.48%). This difference is likely because of the higher number of private alleles observed in *Sfr*. Hence, sample site accounted for a significant portion of the variation in *Sfr* (F-ratio = 3.14, df 11,2415,

TABLE 3.

Pairwise F_{ST} distances and their significance for A, *Pab* and B, *Sfr*. Values above the diagonal indicate significance of each pairwise F_{ST} at $P < 0.05$, after Bonferroni correction, with an asterisk (*) indicating significant and “ns” non-significant tests. F_{ST} values are shown below the diagonal. Site names are abbreviated from Table 1, and abbreviated region names are indicated above the site names. Note that the regions within Washington (WA) are not shown for the two WA sites.

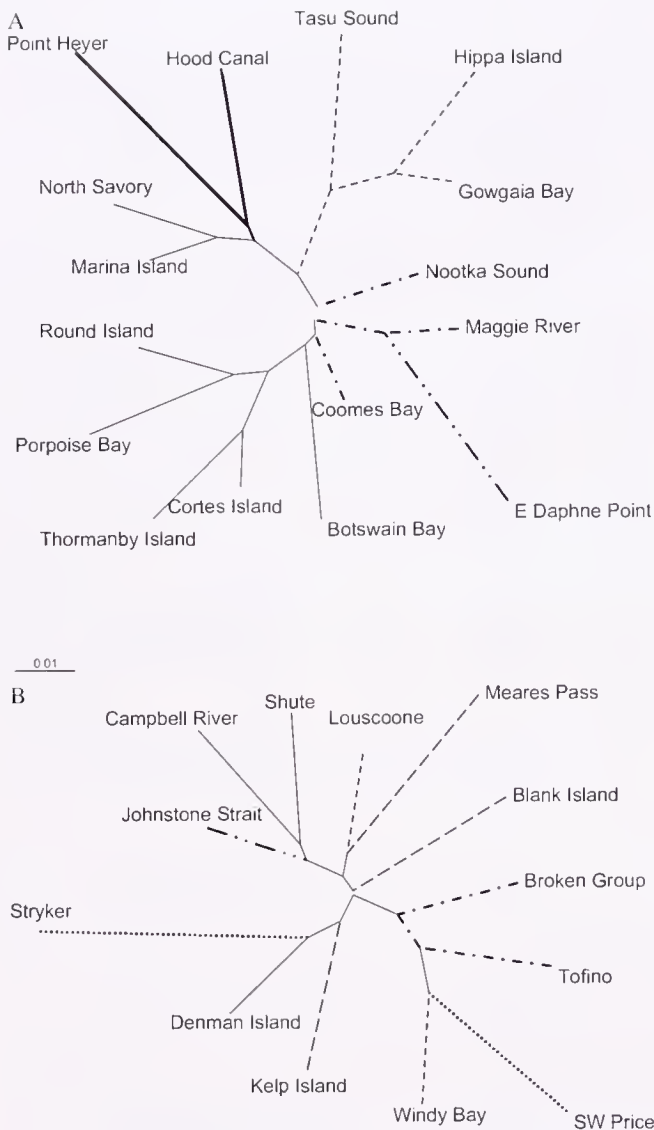

Figure 2. Neighbor-joining dendrogram based on Nei's (1978) genetic distances among A, *P. abrupta* and B, *S. franciscanus* collection sites. Regions are delineated through line type within the dendrogram, with thick solid line for Washington (*P. abrupta* only), thin solid line for ECVI, line-dot-dot for WCVI, line-dot-dot-dot for N-ECVI, short dashed line for QCI, dotted line for central coast (*S. franciscanus* only), and long dashed line for Alaska (*S. franciscanus* only).

$P = 0.0003$). However, no strong geographic clustering of *Sfr* samples was observed in the neighbor joining dendrogram (Fig. 2B), nor was regional structure supported in hierarchical gene diversity analysis (North/South regions, F-ratio = 1.44, $df1,11$, $P = 0.26$). Given that the highest pairwise F_{ST} value (0.007; $P = 0.01$, not significant after bonferroni correction) was observed between the two north coast populations, South West Price Island and Stryker Island, that are only 40 km apart, it is not surprising

that an IBD model of structure was also not supported ($R^2 = 1.07$, $P = 0.36$; FSTAT; Fig. 3B).

DISCUSSION

Current and potential culture operations for geoduck clams and red sea urchins in BC generally aim to enhance harvestable populations (Alan Campbell, pers. comm.). The degree of genetic risk to wild populations associated with these activities is largely influenced by: (1) the degree of assimilation of cultured releases into natural populations; (2) genetic differences between the natural and supplementation populations and (3) the degree of substructure of the natural population (Utter & Epifanio 2002). Our spatial analysis of microsatellite variation in *Pab* and *Sfr* provide the first view of substructure in natural populations of these species in BC, although additional sampling over time will be required to verify conclusions about stable population structure. In addition, data from this study provide a basis for the monitoring and evaluation activities recommended by Utter & Epifanio (2002).

For *Sfr* in BC, we found no evidence of a stepping stone pattern of connectedness (IBD model). Although the lack of geographically-based structure and "randomly" distributed private alleles could fit a model of chaotic genetic patchiness, more data focusing on genetic variation among settling cohorts would be required to provide strong support for this model. In general, our data do not refute the null hypothesis of genetic panmixia of *Sfr* within BC and SE Alaska.

Previous genetic studies of *Sfr* have focused on the southern portion of their range (Edmands et al. 1996, Debenham et al. 2000, Moberg & Burton 2000). Our results are consistent with these studies and with genetic studies of other sea urchin species. Generally, panmixia is not rejected at macrogeographic scales (Palumbi & Wilson 1990, Palumbi & Kessing 1991, Debenham et al. 2000, Addison & Hart 2004), but chaotic genetic patchiness is often observed at microgeographic scales (1–200 km) (Edmands et al. 1996, Flowers et al. 2002). None of the studies to date have supported an IBD model of structure. However, genetic structure caused by phylogeographic boundaries was observed in three species (Mladenov et al. 1997, Addison & Hart 2004).

Patterns of geographical genetic differentiation may reflect events in the distant past (thousands to millions of years ago) as much or more than ongoing patterns of dispersal (Brown et al. 2001, Hellberg et al. 2002). Hence, whereas the lack of genetic differentiation of *Sfr* within BC is consistent with significant gene flow over evolutionary time (thousands of years), recruitment data suggest that over ecological time (tens to hundreds of years), sites may not be as connected by larval dispersal as they appear (Ebert et al. 1994). Recruitment of *Sfr* is sporadic, with large pulses of recruitment occurring only every 3–5 y (ibid), and variation in the distribution of size classes among sites indicates high variability in recruitment over small spatial scales (0.5–8 km) (Sloan et al. 1987). These observations suggest that over ecological time scales, exchange among sites may be more limited than genetic analyses suggest.

Pab inhabits coastal and estuarine sites from California to Alaska and may occur in small numbers in southern Japan (Coan et al. 2000). *Pab* can be found in the low intertidal zone down to depths of 100 m (Goodwin & Pease 1989). We observed a higher level of spatial genetic structuring in *Pab* among the BC sites than reported among sites within Puget Sound and between Puget Sound and an Alaskan site by Vadopalas et al. (2004).

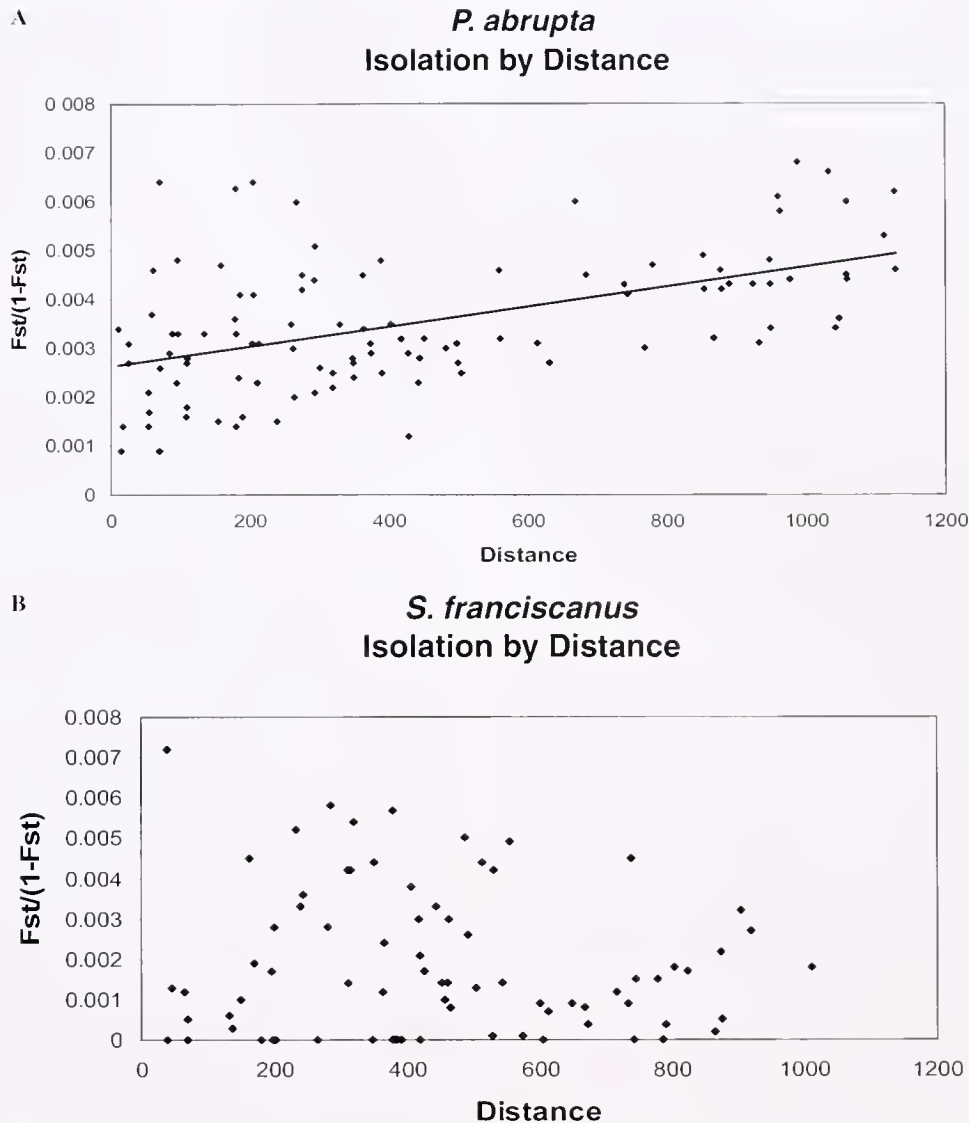

Figure 3. Isolation by distance in A, *P. abrupta* and B, *S. franciscanus*. Distance is the minimum waterway distance in km. The R^2 for *P. abrupta* was 25.5, and was highly significant ($P < 0.0001$). The R^2 for *S. franciscanus* was 1.07 and was not sig ($P = 0.36$).

Although different microsatellite loci were examined in the two studies, both included *Pab* 5 and *Pab* 6. The F_{ST} values for *Pab* 5 and *Pab* 6 were higher in BC (0.005 and 0.003, respectively) than in Puget Sound (0.001 and 0.0001, respectively), indicating greater genetic variability among BC than Puget Sound sites. Whereas the overall geographic range of the two studies was similar, the IBD structure resolved in our study was not supported in the Vadopalas et al. (2004) study. This discrepancy is likely because of differences in the sampling distribution of the two studies: most of the samples in Vadopalas' study were collected within 200 km of one another within the Puget Sound basin and only a single distant Alaskan sample was compared, whereas the samples in our study were more evenly distributed across a span of over 1,100 km, with an average pairwise distance among sites of 445 km. By combining the data from both studies, we can conclude that *Pab* exhibits panmixia at small spatial scales of 50–300 km, and stepping stone gene flow at intermediate scales of 500–1,000 km.

The only *Pab* sites that did not cluster regionally were Marina and Savory Islands, which are located adjacent to one another in

the Strait of Georgia (ECVI) but clustered with Puget Sound instead of other ECVI sites. Both of these sites were exposed to heavy commercial fishing in the past, and the Marina Island population was so depleted that in 1990 it was closed to fishing and became a research site (Campbell et al. 2004). In the mid 1990s Marina and Savory Islands underwent intensive reseedling efforts, with records indicating that broodstock were collected locally (ibid). However, seed from Puget Sound hatcheries was used in reseedling some west coast Vancouver Island sites at a similar time. Thus, the apparent genetic similarity of the Marina and Savory Island samples with Puget Sound samples observed in this study may indicate the introductions records for these two sites are not complete.

Genetic differentiation between rockfish species inhabiting sites in southern Puget Sound and Strait of Georgia/Strait of Juan de Fuca (collectively called the Georgia Basin) (Stout et al. 2001, Buonaccorsi et al. 2002) indicates that the shallow sill at Admiralty Inlet and complicated bathymetry within Puget Sound lead to larval retention within the Sound. For most species, insufficient sam-

pling has been conducted to define the precise location of the biogeographic boundary (Stout et al. 2001, Vadopalas 2003, Vadopalas et al. 2004). Although little differentiation was observed among most pairs of sites in Vadopalas et al. (2004), the sample from Juan de Fuca Strait was distinct from Puget Sound sites. Our study did not contain a sample from the Juan de Fuca Strait, but sites within Puget Sound were significantly differentiated from 6/8 ECVI sites and all sites located in other BC regions. Further, 16/21 comparisons between ECVI and WCVI were significant. Given the vastly different ecological environments between ECVI and WCVI (one wave swept, one sheltered), genetic exchange between these waters may be further limited because of adaptive constraints.

In northern BC, the marine biota of the QCI tend to be distinctive from southern coastal areas (Arndt & Smith 1998, Kyle & Boulding 2000, Withler et al. 2003) due either to the existence of historical refugia or to isolation of the QCI from the mainland by eddies in Hecate Strait (Briggs 1974, Allen & Smith 1988, Hetherington & Reid 2003, Di Lorenzo et al. 2005). The distinction of the QCI region was also relatively well supported for *Pab* in our study, and we hypothesize that oceanographic factors (i.e., disjunction between the California Current and the Alaska Gyre located just south of QCI) have limited recent migration of *Pab* between QCI and more southerly sites. Whereas we cannot discount completely the possibility that historic recolonization was also a factor in the generation of a genetically distinct QCI population, the lack of private alleles and statistical support for QCI as a distinct region in hierarchical diversity analysis suggests that the differences observed are not deep enough to have been derived through historical isolation. This is an important point because statistical support for the IBD structure in *Pab* was dependent on the inclusion of the QCI sites, and if historical events have influenced their relationships, then true stepping-stone gene flow is not necessarily occurring. However, future analyses using data from a broader geographic range of sites and markers could be used to test this hypothesis.

For *Pab*, we suggest the adoption of at least 3 management areas within BC (QCI, Georgia Strait, and west coast Vancouver

Island) and one for Puget Sound. This regional structure corresponds well with five general shellfish transfer zones proposed for BC by the Introductions and Transfer Committee (Dorothee Kieser, Fisheries and Oceans Canada). These zones are Haida Gwaii (our QCI), Georgia Strait, West Coast Vancouver Island, Queen Charlotte Strait (represented by a single sample in our study, E. Daphne Point) and the north/central coast (not sampled in our study). Additional *Pab* sampling from the Queen Charlotte Strait and north/central coasts of BC is required to examine population structure in these regions.

For *Sfr*, the genetic data provide no evidence of strong substructuring within BC waters but do not preclude the presence of geographically-based adaptive differences in growth and survival in the wild. We recommend that at least two management areas be identified within BC associated with the bifurcation of the Subarctic Current into the California and Alaska currents off the west coast of Vancouver Island, and the likely influence of these current systems on recruitment and productivity of marine organisms. *Sfr* culture in northern BC should be conducted with organisms originating within the Haida Gwaii and north/central coast shellfish transfer zones, whereas those in southern BC should be based on organisms originating from waters contiguous with Vancouver Island (i.e., Queen Charlotte Strait, Georgia Strait and west coast Vancouver Island zones).

ACKNOWLEDGMENTS

The authors thank Alan Campbell and two anonymous reviewers for constructive advice relating to the manuscript. Urchin sample collections were coordinated by the Pacific Underwater Harvesters Association (PUHA), Alan Campbell and Dominique Bureau from the Fisheries and Oceans, Canada and Kyle Hebert from the Alaska Department of Fish and Game. Geoduck sample collections were coordinated by the Underwater Harvesters Association (UHA), Fan Seafoods, Island Scallops Ltd. and the Washington Dept. of Fish and Wildlife. This research was funded by the Department of Fisheries and Oceans, Canada through a Canadian Biotechnology Strategy Grant and industry partners, PUHA and UHA.

ABSTRACT In the scope of expanding seeding operations of juvenile scallops (*Placopecten magellanicus*) around Îles-de-la-Madeleine (Quebec, Canada), this study assesses the influence of substrate on growth, survival, dispersal and predation rates in controlled experiments. Three substrates were tested: gravel, sand and sand with empty scallop shells (to investigate the feasibility of modifying the substrate as a management strategy). Dispersal rates were studied with a substrate choice experiment. Predation experiments with two major scallop predators, the rock crab *Cancer irroratus* and the sea star *Asterias vulgaris*, were carried out on different substrate types. No significant difference in growth was observed among substrates and no mortality was observed during the experiment. This suggests other factors, such as hydrodynamics, may be more important than substrate. The dispersal rate was significantly greater on sandy substrate, whereas gravel and sand–shells had similar results. Crab predation was lower on the more heterogeneous substrate (i.e., gravel) whereas, sea star predation was lower on sand. Modifying the natural sand substrate by adding scallop shells could improve seeding success because it diminishes dispersal and predation by crabs.

KEY WORDS: scallop, *Placopecten magellanicus*, seeding, mortality, growth, dispersal, substrate, predation, *Cancer irroratus*, *Asterias vulgaris*

INTRODUCTION

To restore the overexploited population of sea scallop *Placopecten magellanicus* (Gmelin 1791) around Îles-de-la-Madeleine (Quebec, Canada), an experimental restocking program was launched in 1993. After the pilot phase, commercial seedings started in 2000 with the intent to seed 35–50 million young scallops annually. However, because of the expected expansion of the program, the availability of substrate suitable for growth, survival and retention of seeded individuals is likely to become an issue. Around the islands, 70% of the substrate in the scallop habitat depth range (9–55 m) is sandy.

Substrate characteristics influence scallop survival and growth. Whereas adult sea scallops are found on various substrates, gravel and pebbles are the most suitable (Thouzeau et al. 1991a, Stokesbury 2002, Kostylev et al. 2003). Fine particles such as silt decrease survival rate (Yamamoto 1957), and sandy substrate may increase juvenile mortality (Stokesbury & Himmelman 1996, Cliche et al. 1994). In natural conditions, fine inorganic material that is easily resuspended in the water column by currents or wave action is known to have a negative impact on growth in some scallop species (Gruffyd 1974, Bricelj & Malouf 1984). Emerson et al. (1994) demonstrated that high concentrations of seston inhibit sea scallop growth. Nevertheless, substrate heterogeneity has a positive effect on scallop growth. Turbulence created by a heterogeneous bottom may cause local seston accumulations by slowing down the current (Pilditch et al. 1998). A decreasing current speed may improve scallop filtering efficiency, because scallop growth is inhibited in strong current conditions (Bricelj & Shumway 1991, Wildish & Saulnier 1993).

Substrate type is also an important factor for scallop dispersal, as demonstrated by several authors (Winter & Hamilton 1985, Barbeau et al. 1996, Stokesbury & Himmelman 1996, Arsenault et al. 2000). Young individuals are active swimmers (Manuel & Dadsell 1991), but they also must attach themselves to the bot-

tom with a byssus (Hatcher et al. 1996), which reduces dispersal and limits the displacement out of a suitable substrate (Caddy 1972). Therefore, hard substrates possess characteristics that limit juvenile scallop displacement (Caddy 1972, Thouzeau et al. 1991b, Parson et al. 1992, Hatcher et al. 1996). It has been observed that dispersal rates and swimming activities of *Chlamys islandica* and *P. magellanicus* are higher on sand (Stokesbury & Himmelman 1996, Arsenault et al. 2000).

The major cause of scallop mortality on the bottom is known to be predation by rock crabs (*Cancer irroratus*, Say) and sea stars (*Asterias vulgaris*, Verrill) (Barbeau et al. 1994, Hatcher et al. 1996, Nadeau & Cliche 1998). Seeded scallops may have a better chance of survival on heterogeneous substrates: they are less exposed to predators because they can hide in crevasses. Wright (2002) showed that scallops preferentially settled on heterogeneous substrates like pebbles when they were alone or in the presence of crabs. In addition, increasing particle sediment size tended to decrease the predation rate of sea stars on small scallops (11–15 mm) but not crab predation (Wong & Barbeau 2003).

The main goal of this study is to determine juvenile *P. magellanicus* survival, growth and dispersal on 3 different substrates (sand, gravel and sand with scallop shells) in laboratory experiments. In addition, the predation rate by rock crab (*C. irroratus*) and sea star (*A. vulgaris*) in relation to the substrate type was examined.

MATERIAL AND METHODS

Juvenile scallops came from the stock prepared for the 2002 commercial enhancement off Îles-de-la-Madeleine. They were kept in experimental tanks individually supplied with filtered circulating seawater at ambient salinity and temperature. The water passed through a pool filter loaded with sand-blast sand size # 0 and 1, diameter 0.4 mm to 2 mm. The flow rate was adjusted to allow the water in the tanks to be renewed twice daily. Therefore, current velocity in tanks was very low. Temperature was monitored daily from 2002/05–2002/11 and varied between 2.9°C and 23.2°C. Total suspended particulate matter in the water circuit was measured

weekly ($2.53 \pm 1.54 \text{ mg} \cdot \text{L}^{-1}$, mean \pm SE, $n = 100$). Light followed the natural photoperiod, with the intensity dimmed to simulate bottom luminosity.

Survival and Growth

Scallop growth and survival were studied on 3 substrate types: gravel (D50 [median particle size of the sample] = $8400 \mu\text{m}$), sand (D50 = $336.5 \mu\text{m}$) and sand with complete scallop shells (superior and inferior valves; shell height = $113 \pm 2 \text{ mm}$, mean \pm SE, $n = 33$) covering about 25% of the tank bottom. Experiments lasted 88 days, from 2002/05/30–2002/08/26 and water temperature varied between 9.8°C and 23.2°C . Four replicates of each treatment were distributed randomly in twelve 160-L tanks (0.8 m length \times 0.5 m width \times 0.4 m height) (Fig. 1a,b). Each tank represented one trial. Scallop ($25.0 \pm 0.1 \text{ mm}$ shell height, mean \pm SE, $n = 177$) were tagged a few days before seeding with Hallprint plastic tags ($4 \text{ mm} \times 9 \text{ mm}$) fixed with Bostik cyanoacrylate adhesive glue. The plastic tags were also used to fix a monofilament nylon line on each scallop. In each tank, 15 scallops were tethered with a 12-cm monofilament nylon line tied with a solid glued knot onto a galvanized clamp hidden 5 cm in the substrate. This system was designed to avoid scallop settlement along the tank walls. Live scallops were counted once a week.

Growth rate was calculated as the size increment between the beginning and the end of the experiment.

Dispersal

Dispersal was assessed with a substrate choice experiment (M. Fr  chette, Maurice Lamontagne Institute, pers. comm.) in three 1,500-L tanks (2.4 m length \times 1.2 m width \times 0.6 m height) (Fig. 1c,d). The tested substrate was laid in the middle of the tank, covering a surface of $1.20 \text{ m} \times 0.60 \text{ m}$ (0.70 m^2) and surrounded by the reference substrate around the perimeter of the tank (0.70 m^2). In a preliminary experiment, conducted at the average temperature and with each substrate type, indicated random scallop displacements and no location preference was observed (pers. obs.). Three treatments were used: gravel as tested substrate with sand as reference, sand as tested substrate with gravel as reference and sand with 25% of the area covered with entire scallop shells (shell height = $110 \pm 3 \text{ mm}$, mean \pm SE, $n = 21$) as tested substrate with gravel as reference. Thirty juvenile scallops (25 mm shell height, $n = 1075$) were seeded on the central zone from a basket maintained above the water surface. Each trial, carried out on the three treatments simultaneously, lasted 54 h; 12 replicates were done for each treatment. Scallops that stayed on the tested substrate were counted regularly (T0, T2, T4, T6, T8, T12, T24,

Figure 1. Set-up of tanks: (a) upper and (b) lateral views of the tanks system used for growth experiment, (c) upper and (d) lateral views of the tanks system used for dispersal and predation experiments.

T36, T48, T54 h). The experiment took place between May 24, 2002 and July 8, 2002, and water temperature varied from 8.6°C and 19.5°C. During the last seven replicates of the dispersal experiment, the position of the scallops (on the sand, or under or over shells) and the status (byssally attached or not) on the sand-shell substrate was noted.

Predation

An experiment was conducted from September 17, 2002 to September 26, 2002 (water temperature from 13.3°C to 17.5°C) to evaluate predation on juvenile scallops by crabs and from October 15, 2002 to November 14, 2002 (water temperature from 2.9°C to 10.2°C) to evaluate predation by sea stars. Scallops used for these experiments were 28.0 ± 0.1 mm shell height (mean \pm SE, $n = 720$ scallops). Three 1500-L tanks (2.4 m length \times 1.2 m width \times 0.6 m height) (Fig. 1c,d) with a single substrate (gravel, sand or sand with scallop shells) were used. Tank size was expected to avoid limitations in escape responses because of tank's walls. Two predator species were considered: the rock crab, *Cancer irroratus* (92 ± 1 mm carapace width, mean \pm SE, $n = 41$) and the sea star, *Asterias vulgaris* (74 ± 2 mm radius, mean \pm SE, $n = 87$). Both predators were collected off Îles-de-la-Madeleine by a Digby-type scallop drag and acclimated to laboratory conditions for 1 month before the experiment. Predators were kept in perforated baskets (4 per basket) in a tank with filtered circulating seawater and fed twice a week with two mussels (*Mytilus edulis*) or two clams (*Mya arenaria*) per predator. Only male crabs were used to avoid sex-related biases. Predators were starved 48 h prior to the beginning of the experiment. During the crab experiments, two crabs were introduced into the tank 24 h after juvenile scallops had been added ($n = 30$ per tank). Survivors were counted every 4 h until the end of the 12-h trial. For sea stars, four predators were used in a 96-h trial and their positions were noted at each observation time. Scallop survivors in each substrate treatment were counted every 24 h. Predator sizes and time periods were based on the results of preliminary experiments carried on for each predator (Nadeau et Cliche 1998). Four replicates of each substrate treatment were done for the crab and sea star experiments. During the trial, it was difficult to determine whether scallops were hidden or consumed by predators. Therefore, to avoid possible bias, scallops were removed at the end of each trial to count the number of survivors. The position and status (alive or dead) of scallops present on the sand-shell substrate were noted at each observation time.

We based our analysis of scallop reactions on the classification of their positions at the end of the trial: (1) in contact with a hard part of the substrate (shells or attached to a neighboring scallop); (2) in contact with shells only (attached or not; under or over a shell); (3) attached to hard part of substrate and (4) located under a shell but not necessarily attached to it (refuge use). Here we use "in contact" to describe scallops touching a hard substrate, whether they are attached or not. The first two categories identified the frequency at which scallops were using a hard surface in the presence of a predator and if shells were "preferred" or not. The third category determined the proportion of scallops in contact with a hard substrate but also byssally attached to it; this category defined a subset of scallops in the category one. The fourth category was used to define the proportion of scallop shells used as refuges; this category defined a subset of the category two. The proportion of hidden live scallops also served to compare the use of refuges in the presence of crabs and sea stars.

Statistical Analysis

Statistical tests were done with Systat 10.2 software with a probability level (α) of 0.05. No statistical test was necessary for the analysis of survival data without predation because there were no mortalities. Growth data were analyzed using a 2-factor nested ANOVA with substrate (3 levels) as the fixed factor and tank (12 levels) as the random factor nested into the substrate. Normality was assessed using a 1-way Kolmogorov-Smirnov test and homogeneity of variances by a Levene test. The dispersal data were analyzed using 1-way ANOVAs with substrate (3 levels) as the fixed factor (1 per hour). The number of scallops present on the tested substrate (located in the middle of the tanks) at each observation time was used as the dependant variable. Normality was assessed using a 1-way Kolmogorov-Smirnov test and homogeneity of variances by a Cochran test (Critical C: 0.8709). One-way ANOVAs were used for crab and sea star predation data at the end of the experiment, with substrate as a factor (3 levels). This was done separately for each predator species. Normality was assessed by a 1-way Kolmogorov-Smirnov test and homogeneity of variances by a Levene test. A posthoc Tukey test was applied on the results to test specific differences when ANOVAs showed significant effects.

RESULTS

No mortality was observed during the survival and growth experiments without predators. Growth did not differ significantly between substrates (ANOVA: $F_{(2, 168)} = 1.62$, $P = 0.852$). Growth rate was $1.5 \pm 0.1 \times 10^{-1}$ mm \cdot d $^{-1}$ (mean \pm SE) on sand-shells, $1.5 \pm 0.1 \times 10^{-1}$ mm \cdot d $^{-1}$ on gravel and $1.5 \pm 0.1 \times 10^{-1}$ mm \cdot d $^{-1}$ on sand (Fig. 2). Tank had a significant effect on growth (ANOVA: $F_{(9, 168)} = 10.07$, $P < 0.001$). Growth differences were noted in relation to tank position in the water circuit (i.e., growth rate was lower in the middle than at the water inflow and outflow). This indicates that the system used may have created a bias as the slowest growth was observed in the middle section. All tanks were fed individually but the flow rate in tanks of the middle section was more variable and often difficult to adjust. However, that bias does not affect the general results.

Substrate had a significant effect on scallop dispersal (ANOVA: $F_{(2, 33)} = 3.59$ – 18.78 , $P < 0.05$). Weak dispersal was observed on gravel substrate (Fig. 3). The dispersal of scallops was

Figure 2. Mean growth (mm \pm standard error, $n = 4$) of juvenile sea scallops on gravel, sand and sand-shell over 12 wk (88 days).

Figure 3. Mean hourly abundance (half standard error, $n = 12$) of juvenile sea scallops remaining on each tested substrate (gravel: plain line; sand-shell: dashed line; sand: dotted line).

slightly higher on the sand-shell substrate than on gravel, but the difference was not statistically significant (posthoc Tukey test: $P = 0.32$). Dispersal increased during the first 6 h on those two substrates and stabilized afterward, with only 10 and 17% of individuals moving off of the gravel and sand-shell substrates, respectively. Dispersal on sand was significantly higher than on the other two substrates. This difference was already significant by the second hour of the experiment and remained so until the end ($F_{(2,33)} = 3.59-18.78$, $P < 0.05$). Within the first 6 h, 27% of the seeded scallops moved away from sand, increasing to 40% by the end for the trials. In all treatments, some individuals moved away from the reference substrate and went back to the tested substrate. Fourteen scallops returned to gravel, four to sand-shells and only two to sand.

On sand-shell substrate, $76.8 \pm 3.9\%$ (mean \pm SE) of juvenile scallops were found in contact with hard parts of the substrate and the others were unattached. Of these scallops in contact with hard part of the substrate, $71.6 \pm 9.3\%$ were found in contact with empty shells ($70.0 \pm 12.9\%$ located under shells) and the others with a neighbor scallop. A proportion of $40.1 \pm 8.66\%$ of individuals in contact with hard parts substrate were byssally attached to it.

After 12 h, crab predation was highest on sand (mean \pm SE, $n = 7$: 9.3 ± 2.6 live scallops, i.e., 69% of scallops eaten) and lowest on gravel (22.8 ± 1.5 live scallops, 24% of scallops eaten) (Fig. 4). Survival on sand-shell was similar to that on gravel, with 20.8 ± 4.4 live scallops (30% of scallops eaten). However, the

Figure 4. Mean number of scallops surviving crab predation at each observation time (half standard error, $n = 7$) on the tested substrates (gravel: plain line; sand-shell: dashed line; sand: dotted line).

difference between the three treatments was not significant (ANOVA: $F_{(2,9)} = 3.24$, $P = 0.087$). On sand-shell substrate, 20% to 40% of the scallops were hidden under shells. Crabs are fast-moving predators and required a short time for prey handling, leaving only shell fragments. When crabs were not moving, they were immobile on gravel (often near a corner of the tank) or buried in sand. Crabs often moved shells and seemed to have difficulty discriminating prey from nonprey items. Some scallops were so well hidden that counting was biased, causing an increase in the count of live scallops at the very end of the experiment. Thus, the final number is the most accurate because all scallops were removed and counted.

Contrary to crabs, sea star predation (Fig. 5) after 96 h was lowest on sand (mean \pm SE: 22.8 ± 1.9 live scallops, $n = 7$) and highest on gravel and sand-shells (17.8 ± 2.3 and 17.0 ± 1.1 live scallops, respectively); however, the rates were not significantly different (ANOVA: $F_{(2,9)} = 1.63$, $P = 0.248$). Gravel and sand-shell substrates showed a similar pattern: 41% and 43% of scallops were consumed, respectively, on these substrates after 96 h compared with an average of 24% on sand. The level of predation increased in the following order: sand < gravel \approx sand-shells. Sea stars are slow-moving predators, and the time required for prey handling is longer than for crabs; handling time per prey could last 24 h. Sea stars spent most of their time on the walls of the tanks. When they were not on the tank walls, they were found more often on the gravel substrate (average 1.6 sea stars per trial) and sand-shells (average 1.3 sea stars per trial) than on sand (average 0.8 sea star per trial).

The juveniles' use of scallop shells was different between the rock crab and sea star experiments. The proportion and number of live scallops observed under shells increased with time in the presence of crabs (Fig. 6a), whereas it was relatively stable in the presence of sea stars (Fig. 6b). On average, $29.4 \pm 2.8\%$ (mean \pm SE, $n = 4$) of the live scallops were hidden under shells in experiments with crabs, significantly higher than the average of $10.4 \pm 1.5\%$ with sea stars (Mann-Whitney U -test, $P < 0.0001$).

DISCUSSION

Contrary to previous studies, substrate type in our experiment did not have any effect on juvenile scallop survival because no mortality (without predators) occurred. These differences can be attributed to experimental conditions, such as the low density and low current conditions in our tanks. Higher densities or faster

Figure 5. Mean number of scallops surviving sea star predation at each observation time (half standard error, $n = 7$) on the tested substrates (gravel: plain line; sand-shell: dashed line; sand: dotted line).

Figure 6. Percentage of live scallops found under shells (mean \pm SE, $n = 4$) in the presence of (a) rock crabs and (b) sea stars.

water flow can favor resuspension of fine particles and increase mortality rates, as may be the case in the natural environment.

In our study, substrate type did not have any effect on growth rate. Scallop growth is known to be directly correlated with organic matter input (Kleinman et al. 1996, Pilditch & Grant 1999) and inversely correlated with inorganic matter (Cranford 1995). On heterogeneous substrates, like gravel or sand with shells, the topography may induce local accumulations of organic matter while reducing current velocity (Pilditch et al. 1998). Those accumulations and resulting increase in food availability would enhance scallop growth. The optimal current velocity for scallop filtering activity is $10 \text{ cm} \cdot \text{s}^{-1}$ (Wildish & Saulnier 1993), whereas feeding is totally inhibited in strong currents (Wildish & Saulnier 1993). In our experiment, reduced flow and low organic matter input may have tempered the direct effect of the substrate on growth, suggesting that hydrodynamic conditions prevailing on the bottom may be more important than substrate alone.

As expected, dispersal was significantly different among substrate types, with the highest dispersal rate noted on sand. Adding scallop shells onto the sand induced a dispersal pattern similar to the one observed on gravel. Other studies found that dispersal was related to substrate type. In field experiments, Stokesbury and Himmelman (1995) observed less scallop dispersal when seeding occurred on gravelly and rocky bottoms than on sandy bottoms. The preferential use of heterogeneous substrate is related to juvenile scallop behavior (Hatcher et al. 1996): the juveniles in our study needed a suitable substrate for attachment. When scallops were seeded on sand, they swam until reaching a place to fix themselves, such as gravel or shells. Scallops on gravel spent less

time swimming and tended to remain on the same site. The addition of scallop shells to the sand increased the potential attachment sites, thus reducing scallop dispersal and making this substrate comparable to gravel. On the sand-shell substrate, 40% of the scallops were attached together in groups of two or three or attached to shells. Fr  chette (IML-MPO, pers. comm.) has observed some groups of two or three young scallops attached together on sand. This behavior was also noted on sand in this study, but it was unusual on the gravel substrate. However, the study by Stokesbury and Himmelman (1996) indicates that juvenile sea scallops disperse randomly. In this study, the high level of movements from sand to gravel cannot be attributed to a pure random dispersal. Present results should be completed with other studies to further document scallop's behavior on the various substrate arrangement.

Predation rates were not statistically significant between substrates. Temperature could have been a factor (Barbeau & Scheibling 1994b), but temperature changes in each predator experiment were not sufficiently high to account for those results. Because the number of replicates was low (four), individual behavior of predator could have masked any effect and, thus, a higher number of replicates (which was not feasible here because of technical constraints) could have shown more evident results. Even if not statistically demonstrated, trends, however are clear enough to be interpreted. Crab predation decreased with an increase in substrate heterogeneity, with a lower mortality being observed on gravel. On the sand-shell substrate in the presence of predators, as much as 40% of the live scallops were located under shells. A larger number of scallops used refuges on the sand-shell substrate in the crab experiment and this number increased with time. On sand, only

31% of scallops were still alive at the end of the experiment. There was less predation by crabs on the sand-shell substrate than sand. Crab predation is known to be mostly affected by the encounter rate (predator and prey density) because they are fast-moving and have a low prey handling time (Barbeau et al. 1994, Nadeau & Cliche 1998). Sponaugle and Lawton (1990) observed a higher consumption rate of *Mercenaria mercenaria* on sand than on sand-shell substrate by the crabs *Ovalipes ocellatus* (Herbst) and *Callinectes sapidus* (Rathbun) caused by a higher foraging time on the sand-shell substrate. During our experiment, crabs had difficulty discriminating prey items and nonprey items, as was also observed by Wong and Barbeau (2003). Adding shells to the bottom may increase crab foraging time, and scallop survival may be greater because of the decreasing encounter rate. Crabs are visual and chemodetecting predators and can move fast. The scallop escape response in our crab experiment was passive, scallops closed their valve, as has been observed by Barbeau and Scheibling (1994a and b). The presence of shells diminishes the encounter rate with scallops, and one can expect the same effect on crab predation in natural conditions.

In the presence of sea stars, scallop survival was greater on the sand substrate, unlike the experiment with crabs. Experiments on the sand-shell substrate showed survival values intermediate to survival on gravel and sand. When sea stars were not foraging, they moved along the walls of the tanks. Their foraging time on the gravel and sand-shell was twice as high as on sand, perhaps explaining the high scallop survival on sand. Sea stars are slow moving predators and can easily detect chemical signals of organic substances (Zafiriou 1972, Barbeau et al. 1994, Rochette et al. 1994, Gaymer et al. 2002). This explains why shells did not provide an adequate protection against sea stars, which were able to detect scallops in refuges. In addition, scallops have an efficient escape response from slow moving predators like sea stars, and juveniles have better swimming capacities to escape than adults (Barbeau et al. 1994). In fact, scallops did not use refuges as intensively as with crabs. Sea star predation rate is affected by a decrease, a weakness or a distortion of chemical signals (Rochette et al. 1994) and by the probability of capture on encounter (Barbeau et al. 1994). In natural habitats, shells can induce a distortion in the chemical signal in strong current condition and decrease encounter probability. The low current conditions in our experi-

mental tanks may explain why shells seemed to be less effective against sea stars than against crabs.

In our laboratory experiment, sand appeared to be a suitable substrate for scallop survival and growth that was similar to gravel and sand-shell substrate but less suitable for dispersal and against crab predation. Seeded scallops are more vulnerable to predation and need short-term protection against predators when they are released on the bottom. Scallop shells may increase the suitable area for byssus attachment and may provide some refuge from predators. The positive effect of adding shells to the bottom has already been shown. Guay (2003) found that the richness and the density of most common invertebrates increased on sand by adding scallop shells. That author also observed that 2 predators, *Leptasterias polaris* (Müller and Troschel) and *Hyas araneus* (Linnaeus), were attracted to sand and gravel enriched by shells, but that that attraction was more important on gravel. In field experiments, Pacheco and Stotz (2003) showed that settlement and survival of *Argopecten purpuratus* (Lamarck) was improved by adding crushed and empty shells to the bottom compared with natural bottoms (sand and mud). Thouzeau et al. (1991a) noted that the sand-shell (medium sand with quahog, scallop and surf-clam shells) portion of Georges Bank has a lower density of decapods and sea stars than coarse sediments like gravel and pebbles. The effect of substrate on survival, growth and dispersal of juvenile sea scallops was tested in the present controlled experiments. However, that effect may be different in the natural environment, where hydrodynamic processes and many other biotic and abiotic factors may influence the conditions. Attempts were made to transpose the experimental results to field experiments around Îles-de-la-Madeleine (Bourgeois 2004). Because technical biases occurred, those experiments were unable to provide useful data. Considering the promising results of this study, further research is required to better assess the feasibility of substrate modification to improve scallop seeding success.

ACKNOWLEDGMENTS

The authors thank the Company "Petoncle 2000," which provided the young scallops and raising facilities and Dr M. Barbeau (University of New-Brunswick) for her helpful comments. This project was funded by a special grant from the Quebec Department of Agriculture, Fisheries and Food (MAPAQ).

ABSTRACT Two infaunal species, the purple clam *Amiantis purpurata* and the razor clam *Solen tehuatlchus*, are common species in the 15–20 m sandy bottom sediments between southern Brazil and central Argentina. Both species are food sources for the coastal food web, but the extent of their contribution to this food web is still unknown. Based on stomach content analysis and $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ stable isotope signatures we explored the position of these clams in the food web. Stomach content shows that the ray *Sympterygia bonapartei* and the white croaker *Micropogonias furnieri* prey on entire *A. purpurata* and *S. tehuatlchus*. The stable isotopic analysis confirms this result. The elephant fish *Callorhynchus callorhynchus* and the Brazilian codling *Urophycis brasiliensis* also show values of C and N consistent with those expected from species that are preying on *A. purpurata*. Based on the prediction from the isotopic analysis the clam *A. purpurata* is a food source for the shrimps *Artemesia longinaris*, *Pleoticus muelleri*, the anemone *Antholoba achates* and the gastropod *Buccinanops monilifer*. The gastropods *Adelomelon brasiliana*, *Olivancillaria deshayesi*, *Olivancillaria urceus* and *Zidona dufresnei* also show evidence of consuming *A. purpurata* but with contribution from other species with heavier C content. According to complementary results the razor clam *Solen tehuatlchus* may be this other species. The stable isotopic analysis shows that both clam species are at the base of the consumers in the food web. *A. purpurata* showed lighter C mark than *S. tehuatlchus*, but the N isotopic mark showed higher value but still being within the same trophic level.

KEY WORDS: food web, bivalves, fish, crustaceans, gastropods, SW Atlantic

INTRODUCTION

Two infaunal bivalves, the purple clam *Amiantis purpurata* (Lamarck, 1818) and the razor clam *Solen tehuatlchus* (D'Orbigny 1843), are common species in the coastal (≤ 20 -m depth) sandy bottom of the SW Atlantic. The purple clam is distributed from Espírito Santo, Brazil (20°S) to the Golfo San Matías, Argentina (42°S) (Carcelles 1944, de Castellanos 1967, Scarabino 1977) occurring in high-density patches (maximum abundance: 632 clams m^{-2}) at depths ranging from 10–18 m dominated by 1- or 2-year-classes (Morsan 2003). The razor clam *S. tehuatlchus* (≤ 61 -mm length) shows similar distribution, from Río de Janeiro, Brazil (22°54'S) to Bahía Blanca, Argentina (38°44'S) (Rios 1994, Capitoli 1997). However, the abundance of this species is not truly reflected in the literature, probably because of their deep burrowing habits. There is evidence that both species are important food sources for a number of species in shallow coastal areas but the extent of their contribution to the food web is still unknown.

Several predators have been described for these species based on gut content analysis (Olivier et al. 1968, Radonic 1997). For example, siphon tips of *A. purpurata* are the main food item of the electric ray *Discopyge tschudii*, Heckel 1846 (Arrighetti et al. 2005), which is the regionally most abundant torpediniform species. Also, entire clams are preyed by the fish *Pogonias cromis* (Linnaeus, 1766) (García & Gianuca 1997). However, gut content analysis is limited and may be biased toward larger species that can hold the bivalves for longer time (see Sutela & Huusko 2000, Hyslop 1980) and toward food items recently consumed; moreover, this method cannot provide information on the rate of ingestion and regarding long-term assimilation (Creach et al. 1997).

As an alternative, measurement of stable isotope ratios has

become widely used to define relationships between consumers and their food sources (Peterson & Fry 1987, Michener & Schell 1994, Cabana & Rasmussen 1994), and they have been applied to study foraging, migration and other life history phenomena (Hesslein et al. 1991, Alisauskas & Hobson 1993, Walker et al. 1999, Best & Schell 1996, Hansson et al. 1997, Kline et al. 1998, Griffin & Valiela 2001, McGinnis & Emslie 2001). Stable isotopes are relatively consistently fractionated by biological and physical processes as they pass through food webs becoming heavier by 3‰ to 4‰ for N and by 1‰ to 2‰ for C with each trophic transfer (Peterson & Fry 1987, Cabana & Rasmussen 1994). This fractionation from potential food sources to tissues in consumers has been used to identify trophic relationships. Trophic relationships between motile consumers like fishes and their food sources may depend on size of consumers and foraging patterns. Larger animals are able to feed higher in the food web and often acquire heavier isotopic signatures in their tissues (France et al. 1998, Harvey et al. 2002). Therefore, combining isotope analysis with gut contents can provide a better understanding of trophic pathways, given that some items could be ingested but not assimilated. Also, isotope analysis can provide information on those organisms in which it is not possible to evaluate gut content.

In this study, we used stomach content analysis whenever possible and $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ stable isotope signatures to define the position of the purple clam *Amiantis purpurata* and the razor clam *Solen tehuatlchus* in the food web of the shallow northern Argentinean coastal ecosystem.

MATERIAL AND METHODS

Sampling and Study Areas

The study was performed at the coastal area of northern Argentina (38°20'S) between April 2002 and December 2002. This

*Corresponding author. E-mail: flora@bg.fcen.uba.ar

area is dominated by sandy and sandy-silty bottoms (Cortezzi in Olivier et al. 1968). The community studied is typical of a temperate marine environment where few taxa are dominant over a large number of occasional species. The low diversity of the infaunal assemblages has been described (Olivier et al. 1968, Scelzo et al. 2002). Samples of the two bivalves and of the most representative and abundant organisms coexisting with them were obtained from the study area with bottom trawls using a 2-cm cup net from water depth of 10–18 m. The species sampled were the fishes *Urophycis brasiliensis* (Kaup 1858), *Cynoscion striatus* (Cuvier 1829), *Sympterygia bonapartei* (Müller & Henle 1841), *Micropogonias furnieri* (Desmarest 1823) and *Callorhynchus callorhynchus* (Meuschen 1778); the gastropods *Buccinanops monilifer* (Kiener 1834) *Adelomelon brasiliana* (Lamarck 1811), *Olivancillaria deshayesiana* (Duclos 1857), *Olivancillaria urceus* (Roding 1798), and *Zidona dufresnei* (Donovan 1823); the anemone *Antholoba aachates* (Drayton 1984) and the shrimps *Artemesia longinaris* (Bate 1888) and *Pleoticus muelleri* (Bate 1888).

Stomach Content Analysis

The stomach of 15 *Urophycis brasiliensis*, 35 *Cynoscion striatus*, 11 *Sympterygia bonapartei* and 42 *Micropogonias furnieri* were injected aboard with 10% formaline to stop the digestive process. In the laboratory, the total length of each fish was measured to the nearest mm. To analyze the stomach contents, the digestive tract anterior to the intestine was removed and preserved in 10% formaline. Stomach contents were observed under a dissecting microscope. Additional information was made on the gastro-vascular cavity of *Antholoba aachates* and its associated snail *Adelomelon brasiliana*. This information was complemented by reported information from the same area (i.e., Olivier et al. 1968, Radonic 1997).

Stable Isotopes Analysis

Samples of white dorsal muscle of all fish species were removed and frozen for stable isotopic analysis. Samples were also

obtained from the epibenthic fauna (5 pools of 5 individuals each) for the same analysis. All these samples were dried at 60°C, tissues were ground using a mortar and pestle, and all samples were sent to the University of California-Davis Stable Isotope Facility to determine $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ signatures by mass spectrometry.

RESULTS AND DISCUSSION

Stable isotope analysis shows three trophic levels based on expected N fractionation (3.4‰). The two bivalves *Solen tehuelchus* and *Amiantis purpurata* are at the base of the food web, with $\delta^{15}\text{N}$ values between 10.9‰ and 12.3‰. *S. tehuelchus* has $\delta^{13}\text{C}$ values more depleted than *A. purpurata* but similar N isotope ratios. The fishes *Callorhynchus callorhynchus* and *Cynoscion striatus* and the squid *Loligo gahi* (d'Orbigny 1835) are in the upper trophic level with $\delta^{15}\text{N}$ values between 16.7‰ and 17.5‰. In our study system, stomach content analysis can only be reliable with fishes and anemones. Based on information previously reported and our sampling (Table 1), the ray *Sympterygia bonapartei* prey on siphons of *Amiantis purpurata* and *S. bonapartei*. A similar result was previously found for other ray species, the electric ray *Discopyge tschudii* (Arrighetti et al. 2005). *S. bonapartei* showed C and N isotopic values expected from a clam diet, but N isotope ratios showed high variability and could be the result of a mixed diet of both clam species and some contribution of *Artemesia longinaris* (see Fig. 1, Table 1).

Stomach contents showed that the white croaker *Micropogonias furnieri* prey on entire individuals of *A. purpurata* and *Solen tehuelchus* (Table 1). This fish species showed different isotopic values between juveniles (<30 cm in length) and big individuals (Fig. 1), suggesting a shift in diet during their life cycle. Juveniles have values more depleted in C suggesting a food source other than clams, probably crustaceans or polychaetes (Olivier et al. 1968, Radonic 1997 and stomach content results). Adults, however, showed values that suggest an influence of clams. This shift in diet between sizes for this species was found for other sites (Olivier et al. 1968).

Figure 1. $\delta^{15}\text{N}$ versus $\delta^{13}\text{C}$ (mean \pm 1 SE) for the subtidal sandy bottom food web. *Olivancillaria urceus* (Ou), *Olivancillaria deshayesiana* (Od), shrimp *Artemesia longinaris* (Al), anemone *Antholoba achates* (Aa), white croaker *Micropogonias furnieri* small (Mfs) and large (Mll), shrimp *Pleoticus muelleri* (Pm), gastropod *Adelomelon brasiliense* (Ab), gastropod *Zidona dufresnei* (Zd), gastropod *Buccinanops monilifer* (Bm), ray *Sympterygia bonapartei* (Sb), Brazilian codling *Urophycis brasiliensis* (Ub), elephant fish *Callorhynchus callorhynchus* (Cc), striped weakfish *Cynoscion striatus* (Cs), squid *Loligo gahi* (Lg). The arrow shows expected enrichment in one trophic level.

The Brazilian codling *Urophycis brasiliensis*, and the striped weakfish *Cynoscion striatus* (Olivier et al. 1968, Radonic 1997 and our results; Table 1), did not show clams in their stomachs. Carbon isotope ratios of the striped weakfish *C. striatus* showed no evidence of preying on these clams (Fig. 1). The elephant fish *Callorhynchus callorhynchus* and the Brazilian codling *U. brasiliensis* show values of C consistent with those expected from species that are preying on the purple clam *A. purpurata*, but higher N signatures. This could be the result of a mix diet of items in more than one trophic level for example; in this case they could be feeding on shrimps (as seen by stomach contents) and having some contribution of clams.

For invertebrates it is much more difficult, or just impossible, to recognize items in the stomach content by microscopical analysis. Based on the prediction from the isotopic analysis the clam *Amiantis purpurata* is a food source for the shrimps *Artemesia*

longinaris and *Pleoticus muelleri*, and the gastropod *Buccinanops monilifer*. However, the gastropods *Adelomelon brasiliense*, *Olivancillaria deshayesiana*, *Olivancillaria urceus* and *Zidona dufresnei* also show evidence of consuming the purple clam but with contribution from the razor clam *Solen tehuelchus* (Fig. 1).

One of the few invertebrate species where items in the stomach content can be recognized is the anemone *Antholoba achates* (see Acuña et al. 2003). Our results show that 60% of the weight was *Amiantis purpurata*, whereas the other species contributed with much lower values (*Solen tehuelchus* 5%, *Encope emarginata* 11.5%, *Artemesia longinaris* 11.5%, *Olivancillaria uretai*, *O. Urceus* and *Buccinanops moniliferum* 10%, the hermit crab *Pagurus excilis* 0.6%, *Leucipa patagonica* 0.4% and polychaetes 1.1%). Isotope C and N also showed values expected for a diet mainly on *A. purpurata*. Interestingly, this anemone lives epibiotic on the gastropod *Adelomelon brasiliense* (see Acuña et al. 2003). *Adelomelon brasiliense* is a common inhabitant of the studied area, which preys on *Amiantis purpurata* and *Solen tehuelchus* of all sizes (Cledón 2005). These snails are long-lived and can reach over 200 mm in length (Cledón et al. 2005), which means a high predatory pressure for the bivalves, because no size is out of predation risk and their burrowing in the sediment is not always effective, the snails can also do that (Cledón 2005). The anemone and the snail are at the same trophic level (i.e., same *n* values) but C isotope ratios suggest that their food sources are somewhat different (i.e., the C mark differ). Whereas the anemone showed $\delta^{13}\text{C}$ values expected of a predator feeding on *A. purpurata* and no on *S. tehuelchus*, the gastropod *A. brasiliense* showed $\delta^{13}\text{C}$ values suggesting a diet that incorporates both bivalves at similar proportion. The sea anemone and the snail, although highly associated, do not show evidence of large diet overlap. This fact could be related to the burrowing activity of *A. brasiliense*, whereas *A. achates* would remain in contact with the upper sediment levels (Arrighetti et al. 2004).

In conclusion, the purple clam *Amiantis purpurata* and the razor clam *Solen tehuelchus* are species clearly located at the bottom of the food web. These two species contribute to the diet of some gastropods and sea anemones and to some economically important fish.

³College of Life Science, South China Normal University, Guangzhou 510631, China

ABSTRACT Light and electron microscopical studies were carried out to characterize the hemocytes of the oyster, *Crassostrea ariakensis*. Three types of hemocytes were recognized: granulocytes, large hyalinocytes and small hyalinocytes. The large hyalinocytes and small hyalinocytes were agranular cells. The large hyalinocytes presented thin cytoplasm and high nucleus: cytoplasm ratios. The small hyalinocytes were the most homogeneous in shape and showed round or oval. They have the highest nucleus: cytoplasm ratios and contained very thin cytoplasm. The granulocytes showed abundant cytoplasm and low nucleus: cytoplasm ratios. At the ultra-structural level, the large hyalinocytes cytoplasm contained a variable number of mitochondria, Golgi complex and endoplasmic reticulum. They showed a total absence of cytoplasmic granules or a few small electron-lucid vesicles of different sizes. The granulocytes showed more polymorphic than the agranular cells, with numerous pseudopodia sprouting off their surface. The granulocytes showed similar organelles, but on the contrary they had abundant electron-dense particles or electron-lucent granules in the cell cytoplasm. The small hyalinocytes presented a total absence of cytoplasmic granules and few organelles and only one or two mitochondria were sometimes observed in the cytoplasm. Total hemocyte counts gave a mean (\pm SE) concentration of $2.06 \pm 0.20 \times 10^7$ cells mL⁻¹ of hemolymph. Differential hemocyte counts identified the granulocytes as the predominant cell type, followed by the large hyalinocytes and the small hyalinocytes. The percentages of the three cell types in the hemocyte population of *C. ariakensis* were 68.4%, 21.6% and 9.0%, respectively. The quantitative study of phagocytosis showed that the granulocytes were phagocytic cells and the agranular cells showed a limited phagocytic ability. After the separation in Percoll density gradient, the granulocytes were separated from agranulocytes and pure granulocytes were obtained. However, the separation of different agranular cell types (large hyalinocytes and small hyalinocytes) was not achieved by Percoll or Ficoll gradient centrifugation. Our study provides a morphofunctional basis for the cellular defense mechanisms in *C. ariakensis*.

KEY WORDS: *Crassostrea ariakensis*, hemocytes, granulocytes, hyalinocytes, phagocytosis, separation

INTRODUCTION

Hemocytes of bivalve molluscs play an important and central role in the internal defense, and are known to be involved in other processes like wound and shell repair, nutrient digestion, transport and excretion (Cheng 1981). There have been many studies on the morphology, structure, function and classification of hemocytes in bivalves. The most important reviews of the various morphofunctional aspects of the hemocytes of the whole Mollusca phylum are those of Cheng (1981) and Hine (1999), who identified 2 fundamental hemocyte types in bivalve hemolymph: granulocytes and hyalinocytes (or agranulocytes). The presence of these two types was confirmed in *Mya arenaria* (Huffman & Tripp 1982), *Mytilus edulis* (Pipe 1990), *Mytilus galloprovincialis* (Cajarville & Pal 1995, Carballal et al. 1997a, 1997b), *Mercenaria mercenaria* (Tripp 1992), *Crassostrea virginica* (Ford et al. 1994) and *Ruditapes decussatus* (Lopez et al. 1997a). However, the classification schedules were so varied that three, four or even more morphologically different populations have been proposed by authors for various bivalve species (Moore & Lowe 1977, Cheng & Downs 1988, Hine & Wesney 1994, Nakayama et al. 1997).

The oyster, *Crassostrea ariakensis*, is one of the most important commercial mollusk species in China, whose natural range is from the south China coast through Southeast Asia to the western coast of the Indian subcontinent. In China, the culture of *C. ariakensis* has a long history in the Pearl River Delta, Guangdong Province. In recent years, the mass mortality has occurred in cultivated oysters with a great loss. Some studies revealed that the oysters were infected by the pathogen, a Rickettsia-like organism

(RLO) (Wu & Pan 2000, Sun & Wu 2004). However, no systematic studies have been carried out to investigate the morphology, structure, function and classification of hemocytes of *C. ariakensis*. A better understanding of the defense mechanisms in this bivalve species may lead to practical approaches to control RLOs and to avoid mass damage. Here we report the systematic morphological and structural characteristics of the hemocytes in the hemolymph of the oysters. Phagocytosis and separation of hemocytes by discontinuous density gradient centrifugation were also studied. Our study provides a morphofunctional basis for the cellular defense mechanisms in *C. ariakensis*.

MATERIALS AND METHODS

Hemolymph Collection

The oysters, *C. ariakensis* (length: 6.0–9.8 cm; width: 4.5–6.6 cm; height: 9.0–14.0 cm) were collected from Hailing Bay in Yangxi County of Guangdong Province, China. Approximately 0.5–1 mL of hemolymph was extracted from the posterior adductor muscle of each animal using a 25-gauge needle into an equal volume of either Baker formol–calcium fixative (4% formaldehyde, 2% sodium chloride, 1% calcium acetate) or 0.05 M Tris–HCl buffer (TBS; pH 7.6, containing 2% sodium chloride), or into an equal volume of EM fixative (2% formaldehyde, 2.5% glutaraldehyde, 2% NaCl, 2 mM calcium chloride in 0.2 M cacodylate buffer, pH 7.4), as appropriate. A minimum of 20 samples was used for each immune parameter investigated.

Light Microscopy Observation

To characterize the hemocytes, the staining technique with Hemacolor kit (Merck) on hemolymph smears was carried out to

*Corresponding author. E-mail: wuxz@zju.edu.cn

distinguish the hyalinocytes and granulocytes cells. According to the presence or absence of granules in the cytoplasm of the cells, differential hemocyte counts were carried out on Hemacolor smears, and the percentages of different cell types were calculated.

Total hemocyte counts were carried out with an improved Neubauer hemocytometer using Baker's fixed hemolymph samples. Mean cell parameters (cell diameters and nuclear diameter) were calculated by measuring each cell type on hemacolor stained smears using Motic images system.

Transmission Electron Microscopy

The suspension of hemolymph fixed with transmission electron microscopy (TEM) fixative solution was centrifuged ($\times 750$ g, 10 min). The pellets were washed in Pipes buffer with sucrose for 2 h at 4°C and post fixed in 1% osmium tetroxide in Pipes buffer for 75 min at 4°C. After being washed in Pipes buffer, the cells were embedded in 1.5% agar at 40°C and quickly centrifuged ($\times 1,700$ g, 5 min). Then, the pellets were dehydrated and embedded in Epon. Ultrathin sections, (50–70 nm), were stained with uranyl acetate and lead citrate and examined in a TEM JEOL 100CXII.

Scanning Electron Microscopy

Fresh hemolymph was fixed with glutaraldehyde at 2% (v/v) in Millonig 0.2 M, pH 7.3 buffer solution, washed in buffer, post-fixed with osmium tetroxide at 1% (p/v) and placed in dehydration slides with ethanol and amilum acetate, followed by a critical point desiccation process with CO₂ and a platinum/palladium covering. Observation was done using a JEOL MODEL 1200 scanning electron microscopy (SEM).

Separation of Hemocytes by Discontinuous Density Gradient Centrifugation

Hemolymph (0.5–1.5 mL) was withdrawn from the posterior adductor muscle of each animal using a 25-gauge needle, then collected and diluted 1:1 in a modified antiaggregant Alsever solution (MAS) (20.8 g/l glucose; 8 g/l Na citrate; 3.36 g/l EDTA; 22.5 g/l NaCl in distilled water). The hemocytes were then collected by centrifugation at $\times 640g$ (4°C, 10 min). The commercial Percoll (Sigma) solution was adjusted to 1.100 mOsm by adding NaCl to a final concentration of 0.41% (w/v) and the gradients (10%, 30%, 50% and 70% (v/v)) were prepared in MAS. Oyster hemocyte pellets were resuspended in MAS and layered onto the top of a Percoll gradient composed of 70%, 50%, 30% and 10% Percoll. After centrifugation at $\times 640g$ (4°C, 15 min), the hemocytes present at each density interface were collected separately with a syringe. The hemocytes appearing at interface 30/10% of the gradient were further separated by centrifugation through a Ficoll (type 400, Sigma) density gradient containing 20%, 15%, 10% and 5% (w/v) Ficoll prepared in MAS. After centrifugation, the cells appearing at each density interface were collected separately. The density gradient centrifugation was carried out in 13-mL tubes. Each gradient layer of 2.5 mL of Percoll or Ficoll solution and 2 mL of hemocyte suspension were layered in each tube. Each separated hemocyte subpopulations with Percoll gradient or Ficoll gradient were recovered by centrifugation and washed once in MAS. With Each separated hemocyte subpopulations at the different interfaces were made smears, and rapid hemacolor coloration was used.

Hemocyte Viability Evaluation

The viabilities of the fresh hemocytes collected from the oysters and the separated hemocyte subpopulations by Percoll discontinuous density gradient centrifugation were estimated by the 0.1% (w/v) Trypan blue test.

Phagocytosis of Zymosan

Zymosan (cell walls of *Saccharomyces cerevisiae*, zymosan A, Sigma) suspensions were prepared as described by Bachère et al. (1991). Zymosan particles at 40 mg 10 mL⁻¹ were suspended in sterile sea water (SSW) and boiled for 30 min, then washed twice and suspended in SSW before divided into aliquots and stored at -20°C. The aliquots were thawed and counted in a Mallassez cell immediately before use.

To study the phagocytosis of the external materials by oyster hemocytes, hemolymph from 20 oysters was extracted 1:3 in MAS and pooled. Eppendorf vials containing 1×10^6 hemocytes (he) were prepared, then centrifuged ($\times 200$ g, 10 min, 4°C) to remove MAS. One milliliter of filtered seawater (FSW) containing 2.5% of MAS was then added to the vials. Phagocytosis assays were carried out by adding zymosan (zy) suspensions to the Eppendorf vials. The ratios of zy/he were 5:1. The assays were carried out at room temperature (20–23°C) for 60 min. Smears were performed at the end of phagocytosis assay. Hemocytes were fixed and stained with Hemacolor kit. The percentage of cells with phagocytosed particles was evaluated in 30 random selected microscope fields at a magnification of $\times 1,000$ in the slides.

To study the phagocytosis process with electron microscopy, hemolymph from five oysters was extracted in MAS (1:3) and pooled. Phagocytosis vials consisted of 1×10^6 hemocytes, 5zy/he, and 80 μ L of MAS and FSW to a final volume of 2 mL. These assays were carried out at room temperature (20°C to 23°C) for 60 min. After this time, cells were fixed (1 h, 4°C) by adding 2.5% glutaraldehyde to the phagocytosis vials. Hemocytes were then washed for 2 h, 4°C in 0.1 M PIPES buffer containing 7% sucrose (pH = 7.2), postfixed in 1% osmium tetroxide and embedded in agar and epon. Ultrathin sections (50–70 nm) were contrasted with uranyl acetate and lead citrate.

Statistical Analysis

The SPSS software was used for statistical analysis. Differences in all studied parameters were evaluated by 1-way ANOVA followed by Tukey test for comparisons. LSD test was used for multiple comparisons. Values of $P < 0.05$ were considered significant.

RESULTS

Light Microscopy Observation

On Hemacolor smears, 2 hemocyte types were distinguished by light microscopy: granulocytes and hyalinocytes (or agranulocytes) according to the presence or the absence of cytoplasmic granules. Hyalinocytes appeared to have 2 types: small and large hyalinocyte cells, according to the cell diameter in size (Fig. 1). The granulocytes were abundant and often appeared as either spherical cells (round hemocytes) or amoebocytes (spreading hemocytes) on the smears. The granulocytes contained numerous basophilic or refringent cytoplasmic granules and had small nuclei, which often showed the oval or eccentric shapes. On smears, endoplasm and ectoplasm of the cytoplasm could be clearly distin-

Figure 1. Total hemocyte population of *C. ariakensis* on smears stained with the Hemacolor kit (Merck). G, granulocyte; H, large hyalinocyte; S, small hyalinocyte. Bar, 6.0 μm .

guished in the granulocytes. The ectoplasm presenting some thin pseudopodia showed a hyaline aspect whereas endoplasm was denser and contained cytoplasmic granules (Fig. 2). The large hyalinocytes were less abundant and often showed the round or oval shape. They often had the round and large nuclei in the center

of the cells and reduced acidophilic cytoplasms, generally without granules or with few granules in the cytoplasms (Fig. 1). The small hyalinocytes were the least abundant on the smears. The cells and the nuclei often showed the round shape, and they showed large nuclei and reduced acidophilic and thin cytoplasms. Cytoplasmic granules were seldom observed in the small hyalinocytes (Fig. 1). In addition, multinucleate (2–4 nuclei) hemocytes with cytoplasmic granules were observed on these smears (Fig. 3). These multinucleate structures could be the result of the fusion of granulocytes.

Hemocyte Count and Measurements

Total hemocyte counts gave a mean ($\pm\text{SE}$) concentration of $(2.06 \pm 0.20) \times 10^7$ cells mL^{-1} of hemolymph. A total of 1,016 hemocytes of eight oysters were counted for this study. Differential type hemocytes counts showed that the mean percentage compositions ($\pm\text{SE}$) of granulocytes, large hyalinocytes and small hyalinocytes were 68.4 ± 1.55 , 21.6 ± 1.21 and 9.0 ± 0.74 respectively. Table 1 showed the percentage of three cell types in the hemocyte population of *C. ariakensis*.

Table 2 showed the ranges and mean values ($\pm\text{SE}$) of the cell and nucleus sizes and the nucleus/cytoplasmic (N/C) ratios measured on Hemacolor stained smears. Granulocyte types showed larger sizes and smaller N/C ratios than hyalinocytes. Granulocytes were about 6.8 ± 0.15 μm and ranged from 3.2–9.5 μm . Their nuclei were about 2.08 ± 0.05 μm and ranged from 1.29–4.23 μm . The large hyalinocytes are homogenous in size but smaller than granulocytes, with about 3.8 ± 0.08 μm in diameter ranging from 2.35–6.35 μm . Their nuclei were about 2.20 ± 0.05 μm and ranged from 1.2–3.07 μm . The small hyalinocytes had an average size of 2.05 ± 0.04 μm , ranging from 1.32–2.78 μm . Their nuclei diameter was 1.20 ± 0.03 μm , and ranged from 0.78–1.75 μm . Their N/C ratios were the highest, but different among cells.

The results of the ANOVA comparison indicated a significant

difference for the cell size, N/C ratio and nucleus size. The multiple comparisons with the LSD indicated a significant difference between all hemocyte types for the cell size. However, in the case of the N/C ratio, multiple comparisons indicated no significant difference between the large and small hyalinocytes, and in the case of the nuclear diameter, multiple comparisons indicated no significant difference between the large hyalinocytes and granulocyte types (Table 2).

Electron Microscopy

Electron microscopy permitted us to confirm the occurrence of three hemocyte types: granulocytes, large and small hyalinocytes in the hemolymph of *C. ariakensis*. The large hyalinocytes often showed round or oval shapes, and presented smooth surface. The large hyalinocytes presented the high N/C ratios and thin cytoplasm, which contained a variable number of mitochondria, Golgi complex and endoplasmic reticulum (Fig. 4–6). They showed a total absence of cytoplasmic granules or a few small electron-lucid vesicles of different sizes, some of them probably originating in the Golgi complex or the smooth endoplasmic reticulum (Fig. 4). The nucleus of the hyalinocyte appeared round or oval and often was in a central position of the cell. Some large hyalinocyte nuclei had abundant euchromatin, and some showed abundant heterochromatin in the central and the peripheral positions. The nuclei of some hyalinocytes were surrounded only by small cytoplasmic rim (Fig. 5).

The small hyalinocytes were the most homogeneous in shape and showed round or oval. They had the highest N/C ratios and contained very thin cytoplasm. They showed a total absence of

cytoplasmic granules. The organelles such as Golgi complex and endoplasmic reticulum were not observed in the cytoplasm; however, one or two mitochondria were sometimes observed in the cytoplasm (Fig. 6, 7). The nucleus often appeared oval and held most position of the cell. The nucleus sometimes showed abundant heterochromatin in the central and the peripheral positions (Fig. 6).

The granulocytes showed more polymorphic than the hyalinocytes, and were oval or eccentric in shape. The most prominent features of the granulocytes were the numerous pseudopodia sprouting off their surfaces (Fig. 8, 9, 10), which were suggested related with the phagocytic ability of the granulocytes. Some pseudopodia of the granulocytes were slim and long, however some were thick and short (Fig. 8). Some pseudopodia compected together (Fig. 10). Engulfed vacuoles and residual bodies were also observed in the granulocytes. The granulocytes showed abundant cytoplasm and low N/C ratios. They presented similar organelles but on the contrary had abundant electron-dense particles or electron-lucent granules in the cell cytoplasm. The electron dense granules were spherical, often different in size and measured 0.2–0.4 µm in diameter. The electron-dense granules were composed of a homogenous electron-dense matrix (Fig. 8). The electron-lucent granules were round, with an electron-lucent core, surrounded by an electron-dense membrane unit and often very different in size and measured 0.2–0.6 µm in diameter (Fig. 9, 10). Some electron-lucent granules were rough along the peripheral; some were very smooth along the peripheral. Their nuclei appeared polymorphic such as round shape, kidney shape and bell shape (Figs. 8, 9). They often were in one end of the cells or in eccentric positions in the cell cytoplasm.

Scanning Electron Microscopy Observation

Observation under SEM confirmed the surface structures of the hemocytes. According to the size and the surface structure, 3 hemocyte types could be identified: (1) large cells that were usually round and showed no pseudopodia with relatively smooth surfaces, however, sometimes they showed some tiny refractive inclusions or spherule (Fig. 11); (2) small round cells that were the smallest, they were usually round and showed no pseudopodia with relatively smooth surfaces (Fig. 12); (3) irregular cells that often were irregular in shape and presented abundant tenuous and long pseudopodia they usually appeared irregular twist, poly-angle shapes and honeycomb-like surface structure; the surfaces of these cells were usually with corrugation, spongy projections and surface secretion particles (Fig. 13).

Hemocyte Viability After Separation

The dead cells appeared blue staining with the Trypan blue, and the live cells did not stain with the Trypan blue (Fig. 14). The viability of the separated hemocytes collected from fractions at the interface 10/30% and 30/50% of Percoll gradients were compared with the nonseparated hemocytes. For the total hemocyte popula-

Figure 11. Scanning electron micrograph showed the large round cell was usually round and presented a relatively smooth surface, sometimes presenting some tiny refractive inclusions or spherule. Bar, 1.3 μ m.

Figure 12. Scanning electron micrograph showed the small round cell was the smallest, usually round, having a smooth surface. Bar, 0.6 μ m.

Figure 14. Trypan blue test. The dead cells (d) appeared blue staining with the Trypan blue, and the living (l) did not stain with the Trypan blue. Bar, 6.0 μ m.

tion before separation, the mean cell viability was 86.4%. After separation, the corresponding values for fractions at the interface 10/30% and 30/50% of Percoll gradients were 81.8, 82.8%, respectively. No significant difference (*t*-test) was detected between

the viabilities of the total hemocyte population before separation and any of the two separated cell fractions.

Figure 13. Scanning electron micrograph showed the irregular cell appeared twist in shape or irregular poly-angle shapes and honey-comb-like surface structure. The surface of the cells was usually with corrugation, spongy projections, and surface secretion particles. The surface of the cell had abundant tenuous and long pseudopodia. Bar, 2.1 μ m.

Phagocytosis

In vitro phagocytosis assays showed that among the hemocyte types, the granulocytes showed an important phagocytic activity whereas the hyalinocytes did not. Light microscopy revealed that several zymosans were located inside the hemocytes after 60 min, and a few particles were encircled by pseudopodia. The number of zymosan particles phagocytosed per hemocyte was variable, and $6.24 \pm 0.74\%$, $20.61 \pm 1.19\%$ and $29.07 \pm 1.08\%$ of hemocytes phagocytosed, one, two or three particles, respectively, whereas $39.08 \pm 1.69\%$ of hemocytes phagocytosed four or more particles. Electron microscopy confirmed the intracellular location of zymosan. Particles were found inside phagosomes (Fig. 15), some of the particles partially degraded. Hemocytes containing zymosan had many vacuoles that included degraded products.

DISCUSSION

Morphological criteria were generally used to characterize hemocytes in bivalves, however, the existing nomenclature of bivalve hemocytes is inconsistent, being dependent on the observer and the technique used (Feng et al. 1971, Ruddell 1971a, Ruddell 1971b, Foley & Cheng 1972, Cheng 1975, Cheng 1981, Moore & Lowe 1977, Hawkins & Howse 1982, Rasmussen et al. 1985, Chang et al. 2005). Cheng (1981) presented a morphological scheme based on numbers of cytoplasmic granules, dividing cells into 2 types: granulocytes, cells containing granules that ranged from very few to numerous; and agranulocytes, cells containing few or no granules. In this study, we identified 2 main hemocyte types in *C. ariakensis*, with both light and electron microscopy

Figure 15. Transmission electron micrograph showed Zymosan particles phagocytosed by *Crassostrea ariakensis* haemocyte. Z, zymosan; gr, granule. Bar, 1.5 μ m.

observation: granulocytes and agranulocytes (large hyalinocytes and small hyalinocytes). The granulocytes were characterized by the abundant content of granules, presenting a noncentral small nucleus, spreading with pseudopodia related with the phagocytic abilities. According to the cell size, agranulocytes appeared to have two types: small hyalinocytes and large hyalinocytes. The large hyalinocytes were morphologically characterized by the relatively large and central nuclei surrounded by the small volume of cytoplasm and by few or no cytoplasmic granules. The small hyalinocytes have the least cell diameter and large and central nuclei surrounded by the small volume of cytoplasm with the absence of cytoplasmic granules. Many authors suggested that the hyalinocytes were non-different cells; however, hyalinocytes were classed into 2 types, small and large hyalinocytes, by Xue et al. (2000), which supported our classification. Some studies suggested that it was possible to distinguish acidophilic and basophilic granulocytes according to the staining affinities of the cytoplasmic granules of the granulocytes (Cheng 1975, Cheng 1981, Suresh & Mohandas 1990, Nakayama et al. 1997, López et al. 1997b, Wootton & Pipe 2003, Zhang et al. 2005). However, Xue et al. (2000) found the granulocytes of *Ostrea edulis* contained only numerous basophilic or refringent cytoplasmic granules, in agreement with our study on the staining characteristic of *C. ariakensis* granulocytes.

In addition, the multinucleate granulocytes were observed on smears. These cells have been observed in other mollusks (Sparks & Pauley 1964, Cheng 1981, Anderson 1987, Wootton & Pipe 2003) with light microscopy. They are considered to be the result of a fusion of granulocytes in some pathological conditions such as postmortem changes or rejection of grafts. However, the origin and progress of their forming are not clear.

The ultrastructure of the hemocytes in this study revealed that granulocytes mainly contained two types of granules: electron-dense particles and electron-lucent granules. They were different in size of both types of granules. Furthermore, the granules of different size often existed inside most granulocytes simultaneously. Therefore, granulocytes were not differentiated in this study. Some investigators distinguished the granulocytes in other

bivalve with only small or large granules and classed the granulocytes into large and small granulocytes. They considered that the granulocytes with small or large granules were immature or mature granulocytes, respectively (Klebanoff & Clark 1978, Rasmussen et al. 1985, Pipe 1990). However, we agree with the option of Zhang et al. (2005) that the peculiarity of granules should be determined by their origin or function, not by their size and did not believe that granulocytes with different type of granules were in different development phases, though their origin and functions were not wholly clear.

The ultrastructural study of *C. ariakensis* hemocytes showed that some large hyalinocytes contained nuclei with abundant euchromatin and others contained nuclei with large clumps of heterochromatin. Carballal et al. (1997c) also found this phenomenon, but they suggested that both types of hyalinocytes could belong to a different cell line, one for hyalinocytes and another for granulocytes, or hyalinocytes containing abundant euchromatin might give rise to hyalinocytes with more heterochromatin and granulocytes. However, we consider that maybe the both types of large hyalinocytes are in different development phases of the hemocytes, the large hyalinocytes containing nuclei with abundant euchromatin can give rise to hyalinocytes with more heterochromatin that are overripe. The most granulocytes containing nuclei with abundant euchromatin probably are in their bloom stage and present more phagocytic competence. Maybe some large hyalinocytes containing nuclei with abundant euchromatin also result from the overripe granulocytes after fulfilling their phagocytic functions because the nuclear diameters were not significantly different between the large hyalinocytes and the granulocytes.

There are several theories on bivalve hemocytes renewal and maturation. Moore and Eble (1977) suggested that different hemocytes are maturing stages within a single cell line. Cheng (1981) proposed an ontogenetic model with two cell lines, one for hyalinocytes and another for granulocytes, each originating from a different prohemocyte. Auffret (1988) also suggested this last hypothesis for *O. edulis* and *C. gigas* hemocytes. However, in our study the morphological variability found by light and electron microscopy in the oyster hemocytes do not allow us to confirm any of the previous hypotheses.

Total hemocyte counts showed high variability in the number of circulation hemocytes because the density of hemolymph might vary with different species, age and physical status. Because spreading ability was different between hyalinocytes and granulocytes, results of cell measurements were different according to the method used. Lopez et al. (1997a, 1997b) suggested that fixing hemocytes in suspension before measuring was a better method. In our study, differential hemocyte counts after fixing identified granulocytes as the predominant cell type (68.4%), followed by the large hyalinocytes (21.6%) and the small hyalinocytes (9.0%). In the study of other mollusks, similar results were reported. The granulocytes corresponded to roughly 75% and 66% of the total population of hemocytes and the hyalinocytes corresponded to the remaining 25% and 34% in *Scrobicularia plana* (Wootton & Pipe 2003) and *Argopecten irradians* (Xing et al. 2002) respectively. However, some authors reported the hyalinocytes were the predominant cell type (i.e., granulocytes/hyalinocytes were 44.7%/55.3% and 37.3%/62.7%) in *A. irradians* (Zhang et al. 2005) and *C. virginica* (Hégaret et al. 2003) respectively.

The significant differences of cell size and N/C ratios existed in either hyalinocytes or granulocytes. Granulocyte types showed larger sizes and smaller N/C ratios than hyalinocytes. These fun-

damental features are common to many bivalve species (e.g., *M. mercenaria*; Foley & Cheng 1974, *C. virginica*; Feng 1965, *C. edule*; Russell-Pinto et al. 1994, *M. edulis*; Rasmussen et al. 1985, Friebe & Renwranz 1995, *M. lusoria*; Wen et al. 1994 and *A. irradians*; Zhang et al. 2005).

In SEM, special emphasis had been placed on the surface structure. The observation under SEM confirmed the pseudopodia observed under TEM. Moreover, the irregular cells, large round cells and small round cells under SEM might correspond to the granulocytes, large hyalinocytes and small hyalinocytes observed under TEM.

The quantitative study of phagocytosis showed that there were functional differences between hemocyte types of *C. ariakensis*. The granulocytes were phagocytic cells. On the contrary, the hyalinocytes showed a limited phagocytic ability. Similar results were reported in *M. edulis* (Moore & Lowe 1977), *Tapes semidecussatus* (Montes et al. 1995), *Tridacna crocea* (Nakayama et al. 1997), *C. virginica* (Foley & Cheng 1975, Renwranz et al. 1979), *M. mercenaria* (Foley & Cheng 1975), *Mytilus californianus* (Bayne et al. 1979), *O. edulis* and *C. gigas* (Mourton et al. 1992), *Cerastoderma edule* (Russell-Pinto et al. 1994), *Tiostrea chilensis* (Hine & Wesney 1994), *M. galloprovincialis* (Carballal et al. 1997c) and *A. irradians* (Zhang et al. 2005), but these reports were in contrast with those previously reported by Tripp (1992) on *M. mercenaria*, Lopez et al. (1997b) on *R. decussatus* and Cima et al. (2000) on *Tapes philippinarum*. In the latter species, the authors considered that the agranular hemocytes and granulocytes were both active phagocytes.

Phagocytic hemocytes require considerable amounts of energy in the process from phagocytosis of particles, secretion of hydrolysis enzymes, fusion and decomposition of granules to discharge of wastes. Therefore, phagocytic hemocytes often contained abundant numerous mitochondria, Golgi complex, endoplasmic reticulum, and a great quantity of glycogen. Moreover, abundant granules and many spreading pseudopodia of the phagocytic hemocytes were related to the phagocytic competence.

The role of bivalve hyalinocytes with no phagocytosis is unknown. It is possible that they develop other functions different from phagocytosis because in *Cerastoderma edule* they are involved in rosette formation with sheep erythrocytes (Russell-Pinto et al. 1994) and in other invertebrates, such as the crustaceans, they participate in the coagulation process (Hose et al. 1990).

Density gradient centrifugation is one of the most used techniques for separating molluscan hemocytes into subpopulations.

Different materials have been applied as gradient substrates. Cheng et al. (1980) separated fixed hemocytes of *C. virginica* into several subpopulations by sucrose density gradient centrifugation. Clearly, sucrose is not suitable for separation of live cells, in particular, when the separation aims at studies about cell function, because sucrose solutions cannot keep the same osmolarity at different concentrations. However, Percoll, a colloidal suspension of polyvinylpyrrolidone coated silica particles, has been extensively used for separation of living cells. Some investigators have applied it in separating hemocytes of *C. gigas* (Bachère et al. 1988), *C. virginica* (Cheng & Downs 1988), *Lymnaea stagnalis* (Adema et al. 1994), *M. edulis* (Friebe & Renwranz 1995) and *R. decussatus* (Lopez et al. 1997b) and *O. edulis* (Xue et al. 2000). The results obtained in this study indicated that it was also applicable to the separation of *C. ariakensis* hemocytes. After the separation in this type of density gradient, the granulocytes were separated from agranulocytes and pure granulocytes were obtained. However, the separation of different agranular cell types was not achieved by Percoll gradient centrifugation. The agranulocytes had the low percentage of population of hemocytes and were difficult in adhering on the smears, so the observed agranulocytes were fewer than the granulocytes after Percoll gradient centrifugation. In addition, the granulocytes were very stained because the Percoll was not wholly washed off.

Ficoll has very high viscosity, and Ficoll density gradient had been used to separate the large and small hyalinocytes of the *O. edulis* (Xue et al. 2000). In this study, we also applied the technique of centrifugal elutriation, however, the large hyalinocytes and small hyalinocytes could not be separated in this study. In *O. edulis*, the large hyalinocytes could be separated from the small hyalinocytes, but the separation was not complete. However, the density gradient centrifugation with successive Percoll and Ficoll solutions is a practical technique for molluscan hemocyte separation, although it has different efficiency with the different molluscan hemocytes.

ACKNOWLEDGMENTS

The authors thank the team of Marine and Fishery Bureau of Yangxi County, especially Mr. M.Y. Qiu, Mr. X.B. Zhang and Mr. C.G. Cheng for their assistance with sampling the oysters. This study was supported by NSFC (30170741 and 30371107), Scientific Program of Zhejiang Province (2004C23041) and Key Science Program (KSCX2-SW-302-8) of Chinese Academy of Sciences.

ADVANCED *PERKINSUS MARINUS* INFECTIONS IN *CRASSOSTREA ARIAKENSIS* MAINTAINED UNDER LABORATORY CONDITIONS

JESSICA A. MOSS, EUGENE M. BURRESON AND KIMBERLY S. REECE*

Virginia Institute of Marine Science, The College of William and Mary, Gloucester Point, VA 23062

ABSTRACT The Suminoe oyster, *Crassostrea ariakensis*, has been under investigation since the early 1990s for potential use in restoring the commercial harvest or for aquaculture of oysters in the Chesapeake Bay, USA. Initial studies focusing on *C. ariakensis* documented a significant level of tolerance to the protozoan parasite *Perkinsus marinus*, a pathogen found in almost all reaches of the Bay and widely acknowledged as one of the main reasons for the decline in the eastern oyster, *Crassostrea virginica*, harvest since the late 1980s. *Crassostrea ariakensis* was demonstrated to acquire *P. marinus*, however infection intensities, as measured using Ray's thioglycollate medium assay indices, generally were found to be light. As part of a series of experiments to study potential impacts on the Chesapeake Bay region of pathogens found in *C. ariakensis* in Asia, a challenge experiment was conducted to study the pathogenicity of *Perkinsus olseni* to *C. ariakensis*. During this study, we observed the acquisition of moderate and heavy infection intensities of *P. marinus* in triploid *C. ariakensis* oysters being maintained in the laboratory. Results suggest that there may be some risk of mortality from *P. marinus* if *C. ariakensis* is held under stressful conditions at least in hatchery or laboratory settings.

KEY WORDS: *Perkinsus marinus*, *Crassostrea ariakensis*, PCR, RFTM, oyster

INTRODUCTION

The eastern oyster, *Crassostrea virginica* (Gmelin, 1791), an integral part of the economy and ecology of the Chesapeake Bay, has been in a severe state of decline in recent decades. Two pathogens, *Haplosporidium nelsoni* (Haskin, Stauber & Mackin, 1966) and *Perkinsus marinus* (Mackin, Owen & Collier, 1950), the parasites responsible for the diseases known as MSX and dermo respectively, have contributed significantly to the decimation of the oyster populations in Chesapeake Bay since the 1950s (Sindermann 1990).

The decline in oyster production in Virginia led to the formation of a number of panels in the early 1990s to make recommendations on restoring oyster populations. One option currently being seriously considered is the introduction and use of a nonnative oyster in Chesapeake Bay. A Virginia Institute of Marine Science (VIMS) study conducted in 1996 focusing on the Pacific oyster, *Crassostrea gigas* (Thunberg, 1793), documented lower disease susceptibility in *C. gigas* than in the native eastern oyster, *C. virginica*; however, growth rates of the Pacific oyster were equal to or inferior to the native oyster in the Chesapeake Bay (Calvo et al. 1999). A 1998 field-based study on another Asian oyster, the Suminoe oyster, *Crassostrea ariakensis* (Fujita, 1913), documented rapid growth and survival in that species, as compared with *C. virginica*, even when endemic diseases were prevalent (Calvo et al. 2001). Although initial baseline samples of *C. ariakensis* in that study revealed a 12% prevalence of *P. marinus*, all subsequent samples collected after field deployment showed *C. virginica* with higher *P. marinus* prevalence than *C. ariakensis*. Additionally, Ray fluid thioglycollate medium (RFTM) (Ray 1952) diagnoses showed several heavy *P. marinus* infections in *C. virginica*, however, only light infections were observed in *C. ariakensis* (Calvo et al. 2001).

In this report we describe the first account of moderate to heavy *P. marinus* infections in *C. ariakensis*. The oysters in this study were held in laboratory aquaria at VIMS during a challenge experiment conducted to examine the potential pathogenicity of *Perkinsus olseni* Lester and Davis, 1981, to *C. ariakensis*, because *P.*

olseni was found during a recent survey of *C. ariakensis* populations in Asia (Moss & Reece 2005). Prior to the start of the challenge experiment, *C. ariakensis* were initially determined to be *Perkinsus* sp.-free, based on molecular diagnostics using PCR (Casas et al. 2002). The oysters acquired detectable levels of the parasite, however, after being held for about 8 weeks in the laboratory aquaria. We used the infected oysters in our challenge study, despite baseline *P. marinus* infection prevalence, to examine the potential for *C. ariakensis* oysters to become coinfecting with multiple *Perkinsus* species. We report here our observations regarding the *P. marinus* infection levels observed in *C. ariakensis* during this challenge experiment.

MATERIALS AND METHODS

Experimental Design

On January 24, 2005, 120 market sized (~75 mm shell height) triploid *C. ariakensis* were received from the Aquaculture Genetics and Breeding Technology Center hatchery at VIMS. The animals were held for 4 days inside a plastic mesh bag in a holding tank prior to bringing them into the laboratory aquaria. The holding tank was not covered and there was flow-through of nonfiltered York River water of approximately 9°C and 16 ppt salinity. On removal from the holding tank, 20 *C. ariakensis* were immediately sacrificed, and gill and mantle tissues were excised aseptically from each animal for DNA extraction. Genomic DNA of each oyster was used in a PCR-based molecular diagnostic assay (Casas et al. 2002) to examine the animals for the presence of DNA from *Perkinsus* spp. parasites. The animals were subsequently held for 59 days in 10-gallon glass aquaria that were maintained at 20°C and 25 ppt salinity at a density of approximately 25 oysters per tank and were fed 0.1 g oyster⁻¹ algal food daily (Reed Mariculture, San Jose, CA). At the end of 59 days, on March 24, 2005, five *C. ariakensis* were sacrificed and gill and mantle were excised aseptically from each animal to be used in *Perkinsus* spp. screening by PCR assays as described later.

On March 28, 2005, the remaining *C. ariakensis* ($n = 60$) were used in a challenge experiment designed to evaluate the pathogenicity of *P. olseni* to *C. ariakensis*. Twenty *C. ariakensis* received single pallial cavity injections of 100 µL of 25 ppt sterile artificial

*Corresponding author. E-mail: kreece@vims.edu

seawater (SASW) through a notch in the shell, and 40 animals were inoculated with 10^5 log phase cultured *P. olsenii* cells per gram body weight in a 100- μ L volume. The clonal *P. olsenii* culture isolated from a Japanese *Venerupis philippinarum* (Adams and Reeve, 1850) clam was obtained from Mr. Chris Dungan, Maryland DNR Cooperative Oxford Laboratory, Oxford Maryland, (ATCC PRA-181). Thirty additional untreated, control *C. ariakensis* were neither notched nor inoculated, but held in separate aquaria and otherwise maintained and fed in the same manner as the experimental animals for the duration of the experiment. Those *C. ariakensis* inoculated with 25 ppt SASW were maintained in one 10-gallon aquarium, and those inoculated with *P. olsenii* were split evenly between two aquaria. All aquaria were identical and each tank was covered with a plexiglass lid.

All aquaria environments were maintained at 20°C to 22°C and contained 25 ppt aerated, 1- μ m filtered York River water, two thirds of which was removed each week and replaced with an equal volume of clean, 25 ppt, 1- μ m filtered York River water. Animals were fed daily a single dose of approximately 0.1 g oyster⁻¹ algal feed (Reed Mariculture).

Aquaria were checked daily for oyster mortalities, and moribund animals were removed. The cumulative mortality was calculated for each sample as the sum of the mortalities that occurred during the course of the experiment, which started 59 days after the *C. ariakensis* were brought into the aquaria, divided by the number of live animals at the start of the experiment. When moribund animals were discovered, if adequate undegraded tissues remained they were processed for analysis. Gill and mantle tissues were removed with a portion preserved in 95% ethanol for DNA extraction and molecular diagnostics and gill, mantle and rectal tissues were processed for Ray fluid thioglycollate medium (RFTM) assay (Ray 1952). After 27°C incubation for 5–6 days in RFTM, tissues were removed from the culture tubes, macerated on microscope slides and stained with Lugol iodine. Stained, cover-slipped tissue preparations were examined under a light microscope and *Perkinsus* sp. tissue burdens were enumerated on a scale from rare (R) to very heavy (VH) based on the categories of Ray (1952, 1954). Visceral mass tissue sections were preserved in Davidson's solution for histological analysis (Shaw & Battle 1957).

Experimental Sampling

Because of space constraints in the laboratory, the untreated *C. ariakensis* that were remaining after 37 days were sacrificed and tissues were taken for DNA, RFTM and histological analysis of disease status as described earlier. For those tanks in which *C. ariakensis* were inoculated with either 25 ppt SASW (one tank) or with *P. olsenii* (two tanks), two randomly chosen oysters from each tank were removed and sacrificed for disease diagnosis on days 21, 44 and 59 postinoculation. The challenge experiment was terminated on day 72 and all remaining animals were sacrificed and tissues preserved as mentioned earlier for DNA, RFTM and histological analysis.

Nucleic Acid Extraction

Genomic DNA was extracted from the excised mantle and gill tissue snips, using a DNeasy Tissue Kit (Qiagen Inc., Valencia, CA), following manufacturer's protocols, except that DNA was eluted in a single 200- μ L volume of elution buffer after a 10 min incubation at room temperature (approximately 20°C).

SSU Genes

To assure that PCR amplifiable DNA was present in all extracted samples, genomic DNAs were tested using universal small subunit (SSU) ribosomal RNA gene primers 16S-A (5' CCG AAT TCG TCG ACA ACC TGG TTG ATC CTG CCA GT 3') and 16S-B (5' GGA TCC AAG CTT GAT CCT TCT GCA GGT TCA CCT AC 3') (modified from Medlin et al. 1988) with an expected amplification product of approximately 1,800 bp. Each 25- μ L reaction contained 20 mM Tris-HCl (pH8.4), 50 mM KCl, 0.75 mM MgCl₂, 0.1 mM of each dNTP, 0.5 μ M each primer, 0.0125 U μ L⁻¹ *Taq* polymerase, 0.2 mg mL⁻¹ BSA and 0.5 μ L genomic DNA (~10–50 ng total). Amplifications were performed with an initial denaturation of 94°C for 4 min, followed by 35 cycles at 94°C for 30 sec, 45°C for 30 sec, 65°C for 2 min, with a final elongation of 65°C for 2 min. After amplification, 3 μ L of PCR product were analyzed by agarose gel electrophoresis (2%), stained with ethidium bromide and visualized under UV light. Images were recorded with an Alpha Innotech FlourChem (San Leandro, CA) imaging system.

Genus-specific *Perkinsus* sp. PCR Assay

Screening for *Perkinsus* sp. DNA was performed using *Perkinsus* genus-specific primers, PerkITS-85 (5' CCG CTT TGT TTG GAT CCC 3') and PerkITS-750 (5' ACA TCA GGC CTC TAA TGA TG 3') (Casas et al. 2002) that target the internal transcribed spacer (ITS) region of the ribosomal RNA gene complex. Each PCR reaction contained the following: PCR buffer at a concentration of 20 mM Tris-HCl (pH8.4), 50 mM KCl, 1.5 mM MgCl₂, 0.2 mM of each dNTP each primer at 0.1 μ M, 0.025 U μ L⁻¹ *Taq* polymerase, 0.05 mg mL⁻¹ BSA and 0.5 μ L genomic DNA (~10–50 ng total). Amplifications were performed with an initial denaturation of 95°C for 4 min followed by 40 cycles of 95°C for 1 min, 53°C for 1 min, 65°C for 3 min, with a final elongation of 65°C for 5 min. After amplification, 4 μ L of PCR product were analyzed as described earlier.

Perkinsus Species-specific Assays

Identification of the *Perkinsus* species that was infecting animals shown to have positive amplification products with the *Perkinsus* genus-specific assay was accomplished through the use of *P. marinus* and *P. olsenii* species-specific PCR assays. *Perkinsus marinus*-specific primers PmarITS-70F (5' CCT TTG YTW GAG WGT TGC CAG ATG 3') and PmarITS-600R (5' CGA GTT TGC GAG TAC CTC KAG AG 3') (Audemard et al. 2004) and *P. olsenii*-specific primers designed for this study Pols-140F (5' GAC CGC CTT AAC GGG CCG TGT T 3') and PolsITS-600R (5' GGR CTT GCG AGC ATC CAA AG 3') were used in separate 25- μ L reactions. PCR reactions for the *P. marinus* ITS region contained the following: PCR buffer at a concentration of 20 mM Tris-HCl (pH8.4), 50 mM KCl, 1.5 mM MgCl₂, 0.2 mM each dNTP, each primer at 0.1 μ M, 0.025 U μ L⁻¹ *Taq* polymerase, 0.05 mg mL⁻¹ BSA and 0.5 μ L genomic DNA (~10–50 ng). Amplifications were performed with an initial denaturation of 95°C for 4 min followed by 40 cycles of 94°C for 1 min, 57°C for 1 min, 65°C for 3 min, with a final elongation of 65°C for 10 min. PCR reactions for the *P. olsenii* ITS region contained the following: PCR buffer at a concentration of 20 mM Tris-HCl (pH8.4), 50 mM KCl, 1.5 mM MgCl₂, 0.2 mM each dNTP, each primer at 0.1 μ M, 0.025 U μ L⁻¹ *Taq* polymerase, 0.05 mg mL⁻¹ BSA and 0.5 μ L genomic DNA (~10–50 ng). Thermocycling parameters were as follows: an

initial denaturation of 95°C for 4 min followed by 40 cycles of: 94°C for 1 min, 62°C for 1 min, 65°C for 3 min, all followed by a final elongation step of 65°C for 10 min. After amplification, for each species-specific reaction, 4 µL of PCR product were analyzed as described earlier.

Specificity of *P. olseni* primers was tested against *P. marinus* and *Perkinsus chesapeaki* McLaughlin, Tall, Shaheen, Elsayed and Faisal 2000, DNAs. In addition, amplification products from positive *P. olseni*-specific reactions were sequenced. PCR products were cloned into the plasmid pCR4-TOPO and transformed into *E. coli* using a TOPO TA Cloning Kit (Invitrogen, Carlsbad, CA) following the manufacturer's protocols. Transformed bacterial colonies were picked from agar plates using a sterile wooden toothpick and were inoculated into 10 µL of sterile water in 200 µL plastic strip tubes. Inoculated water samples were boiled for 4 min at 94°C and 0.5 µL of the boiled preparation was used in an M13 PCR reaction using the forward and reverse primers supplied in the cloning kit. Each 25 µL reaction contained the following: 20 mM Tris-HCl (pH 8.4), 50 mM KCl, 1.5 mM MgCl₂, 0.2 mM each dNTP each primer at 1 µM, 0.25 U µL⁻¹ *Taq* polymerase, and 0.2 mg mL⁻¹ BSA. Thermocycling parameters were as follows: an initial denaturation at 94°C for 2 min, followed by 30 cycles of 94°C for 30 sec, 54°C for 30 sec and 72°C for 1 min, followed by a final elongation at 72°C for 5 min. Following amplification using the M13 primer pairs, 3 µL of each PCR product were analyzed as mentioned earlier. Prior to sequencing, PCR products from clones containing the correct insert size were treated with shrimp alkaline phosphatase (SAP) and exonuclease I (*Exo I*) (Amersham Biosciences, Piscataway, NJ), to degrade nucleotides and single-stranded DNA (primers) remaining after PCR. Five micro liters of the M13 PCR product were combined with 0.5 units of SAP and 5.0 units of *Exo I*, and incubated at 37°C for 30 min, 80°C for 15 min, and 15°C for at least 5 s. Clean PCR products from plasmid inserts were sequenced bidirectionally using the Big Dye Terminator kit (Applied Biosystems, Norwalk, CT) with M13 sequencing primers, and using 5-µL reactions with 0.125 times the concentration of Big Dye reagent specified in the manufacturer's protocols. Each 5 µL reaction contained 0.0625 µL of Big Dye, 0.96875 µL of 5x buffer, 1.6 pmol of each primer, and 10 ng of clean PCR product. Thermocycling parameters were as follow: 25 cycles of 96°C for 1 min, 96°C for 10 sec, 50°C for 5 sec, 60°C for 4 min, followed by a final incubation at 4°C until the sequencing reaction products were precipitated using the ethanol/sodium acetate precipitation method (ABI User Bulletin, April 11, 2002). Precipitated sequencing reaction products were resuspended in 20 µL of Hi-Di formamide (Applied Biosystems) and 10 µL of each were electrophoretically separated on an ABI 3100 Prism Genetic Analyzer.

RFLP

For further confirmation of the presence of *P. marinus* or *P. olseni* DNA, and to further verify the specificity of the *Perkinsus* species-specific primer sets, genus-specific PerkITS-85/750 amplification products were digested with *Mbo* I restriction endonuclease (New England Biolabs, Beverly, MA). Based on analyzing published and unpublished sequence data of all known *Perkinsus* species, this enzyme will cut the approximately 760 bp ITS fragment of *P. marinus* DNA that is generated in the genus-specific assay to yield a 3-fragment digestion profile unique to this species. The fragments should be approximately 17,226 and 264 bp in length. For *P. olseni*, *Mbo* I should cut the ITS region fragment to

yield a 4-fragment digestion profile with fragment lengths of approximately 64, 85, 251 and 262 bp in length. Each 10-µL digestion reaction contained 5 µL of PCR product, 8.2 µL of sterile distilled water, 1.5 µL of 10X NEB buffer 3, and 0.3 µL of restriction enzyme. As controls, separate oyster genomic DNA samples, determined previously to be infected with *P. olseni* and *P. marinus*, and plasmid-purified *P. chesapeaki* ITS DNA was first amplified with the *Perkinsus* genus-specific primers, Perk-ITS85/750, as described above and then digested with *Mbo* I restriction endonuclease. We chose to use only *P. marinus*, *P. olseni* and *P. chesapeaki* DNAs as controls, because these were the *Perkinsus* species, that we expected might be present in our samples. *Perkinsus olseni* was being used in the experiment and *P. marinus* and *P. chesapeaki* are common to Chesapeake Bay and potentially their DNAs could have contaminated the 1-µm filtered York River water, although this was not likely. PCR products were digested at 37°C for 6 h and 10 µL of the digested PCR product was electrophoresed on a 3% agarose gel that was 1.5% agarose and 1.5% low melt agarose (Fisher Scientific, Raleigh, NC), stained with ethidium bromide and visualized under UV light. Images were recorded with an Alpha Innotech FlourChem (San Leandro, CA) imaging system.

Histological Analysis

Tissues preserved for histological analysis in Davidson's solution (Shaw & Battle 1957) were dehydrated in a series of ethanol baths, infiltrated with paraffin and embedded in paraffin blocks prior to sectioning. Sections of 5-µm thickness were stained with Harris-hematoxylin and eosin. Histological sections of infected oysters were examined using light microscopy to visualize *Perkinsus* sp. parasite cells *in situ*.

In-situ Hybridization

Representative tissue sections from a few of the *C. ariakensis* oysters determined to have *P. marinus* or mixed infections of both *P. marinus* and *P. olseni* by species-specific PCR were evaluated by in situ hybridization (ISH). A genus-specific 5' end digoxigenin-labeled *Perkinsus* probe (Elston et al. 2004) was used to specifically target SSU rRNA sequences. *Perkinsus* species-specific probes, PmarLSU-181DIG (5'-GACAACGGCGAACGACTC-3'), specific to *P. marinus*, and PolsLSU-464DIG (5'-CTCACAAGT-GCCAAACAAGT-3'), specific to *P. olseni*, were designed by locating unique regions in aligned available *Perkinsus* species LSU rRNA gene sequences. Digoxigenin-labeled oligos were obtained from Operon Biotechnologies, Inc. (Huntsville, AL). The protocol followed for ISH was that previously published (Stokes & Bureson, 1995) with the modifications published by Elston et al. (2004). Pronase at a final concentration of 125 µg mL⁻¹ was used for permeabilization during a 30-min incubation, and a probe concentration of 7 ng µL⁻¹ was used for hybridization. The species-specific probes were tested for specificity with numerous *Perkinsus* sp.-infected reference tissues, including *P. marinus* in *C. virginica*, *P. chesapeaki* in *Mya arenaria* Linnaeus, 1758 and *P. olseni* in *Haliotis laevis* Donovan, 1808. Controls for each *Perkinsus* species-specific probe were tested identically except that they received hybridization buffer lacking probe during the hybridization step.

* Species-specific PCR assays indicated that one of these individuals, as well as one *P. olseni*-inoculated individual collected on day 21 (data not shown), contained DNA from both *P. marinus* and *P. olseni*. Only *P. marinus* DNA was detected in all other individuals.

RESULTS

Genus-specific PCR and RFTM Assay Results

All tissue samples used for DNA extraction yielded high quality genomic DNA as indicated by strong 1,800 bp amplification products that were clearly visible by UV illumination of agarose gels following PCR with the SSU rRNA gene universal primers. *Perkinsus* genus-specific PCR-based diagnostic screening of an initial baseline subset of 20 *C. ariakensis* sacrificed on January 24, 2005 showed that all animals were free of *Perkinsus* DNA. After being held in the laboratory aquaria for 59 days, prior to inoculation, five *C. ariakensis* were sacrificed and genus-specific PCR screening indicated a 100% prevalence of *Perkinsus* sp. DNA.

RFTM and *Perkinsus* genus-specific PCR screening results for the *C. ariakensis* that were inoculated with SASW or *P. olseni* cells are shown in Table 1. RFTM data were not collected during the first day of subsampling (Day 21), however the PCR screening indicated the presence of *Perkinsus* sp. DNA in both oysters sampled from those inoculated with SASW and in three of the four oysters sampled from the *P. olseni* injections. There were no *Perkinsus* cells observed by RFTM assays in the day 44 SASW sample, although *Perkinsus* sp. DNA was found by the PCR assay in one of the two oysters sampled. Very light-light RFTM rankings were found for two of the four *P. olseni*-inoculated oysters sampled on day 44 and three of the four were positive in the *Perkinsus* genus-specific PCR assay. On day 59 both of the SASW-inoculated oysters sampled had moderate-moderate/heavy *Perkinsus* sp. tissue burdens and *Perkinsus* sp. DNA was found in both by the PCR assay. Three of the four *P. olseni*-inoculated oysters that were sampled on day 59 had light-moderate infections as indicated by the RFTM assay and *Perkinsus* DNA was detected in all four of the oysters. On day 72, when the experiment was terminated, six SASW- and 15 *P. olseni*-treated oysters remained and were sacrificed. *Perkinsus* DNA was found by the PCR assay in all of the oysters remaining from the two treatment groups (Table 1). *Perkinsus* sp. cells were not detected, however, by the RFTM assay in three of the SASW-inoculated or in one of the *P. olseni*-inoculated oysters. The other three remaining SASW-inoculated oysters had rare RFTM rankings. Rare-light/moderate

tissue burdens were found in nine *P. olseni*-inoculated oysters at the end of the experiment and four *P. olseni*-inoculated oysters had heavy-very heavy infections as indicated by the RFTM assay.

RFTM and *P. marinus* PCR assay results for the 29 untreated *C. ariakensis* that were still alive and were sacrificed on day 37 of the challenge experiment are shown in Table 2. Eighteen of these oysters were ranked as having rare to light *Perkinsus* sp. tissue burdens, two were ranked as light/moderate and two as moderate-moderate/heavy tissue burdens. Seven had no observable *Perkinsus* sp. cells in the RFTM assay, however five of these were positive in the PCR assay. *Perkinsus marinus* DNA, as indicated by the PCR assay, was found in 23 of these 29 untreated oysters (Table 2), with no DNA detected in three of the oysters with a rare RFTM ranking and in one with a light infection as indicated by the RFTM assay.

Mortality Data

Mortality was observed in untreated oysters and in those injected with either SASW or *P. olseni* (Table 3). For the untreated *C. ariakensis*, two died during the 37 day period that they were

Column headings indicate the sample treatments.

held in the aquaria. For the SASW treatment and the *P. olseni* treatment, cumulative mortality after 72 days was 40.0% and 46.2%, respectively. Of the 27 dead *C. ariakensis* removed from the untreated tank and the experimental aquaria during the course of the experiment, it was possible to conduct RFTM analysis on 11 oysters and PCR analysis on 22. All tissues taken from dead *C. ariakensis* were PCR positive for *Perkinsus* sp. DNA. Of these 11 oysters examined by RFTM, 2 had none, or rarely observable *Perkinsus* sp. cells, 2 had very light or light tissue burdens, 1 had a light/moderate tissue burden and 6 had moderate to heavy tissue burdens of *Perkinsus* sp. cells.

Species-specific PCR Screening for *Perkinsus marinus* and *Perkinsus olseni*

DNAs from all oysters shown to be PCR positive with the *Perkinsus* genus-specific assay were analyzed using both *P. marinus*-specific and *P. olseni*-specific primers. Because the *P. olseni* primers were new for this study, specificity was tested against *P. marinus* and *P. chesapeakei* DNAs. The *P. olseni* primers did not amplify DNA from these other *Perkinsus* species. Sequencing of amplification products further confirmed the specificity as sequences of amplification products from all positive *P. olseni*-specific reactions matched those of GenBank deposited *P. olseni* (*P. atlanticus*) sequences. The five *C. ariakensis* taken as a baseline sample immediately prior to the start of the study, and all untreated oysters had only *P. marinus* DNA. In addition, all but two of the *C. ariakensis* that were SASW- or *P. olseni*-inoculated and that were *Perkinsus* sp. positive with the genus-specific primers, were positive for only *P. marinus* DNA. Two oysters that were inoculated with *P. olseni* at the start of the challenge and were sampled on days 21 and 72 were positive for both *P. marinus* and for *P. olseni* DNA. Tissue from all dead oysters collected from either the experimental or untreated aquaria were found to be PCR-positive for *P. marinus* only.

RFLP Results

The *P. olseni* and *P. marinus* positive control DNA isolated from cultured cells, and plasmid-purified *Perkinsus chesapeakei*

ITS region DNA, were amplified in the *Perkinsus* genus-specific assay and were digested with *Mbo* I restriction endonuclease. Results confirmed that *P. marinus* ITS region DNA has a unique digestion profile when digested with *Mbo* I and the observed fragment sizes of approximately 17 bp, 226 bp and 264 bp were consistent with the fragment sizes expected for *P. marinus*.

Histology

Ten animals shown by PCR to have *Perkinsus* sp. DNA, and whose tissues showed light to very heavy RFTM rankings were chosen for further histological examination. A tissue section from one animal with a very heavy RFTM ranking that had died during the experiment showed gross lesions (Fig. 1A) and observable parasite cells when stained with Harris-hematoxylin and eosin (Fig. 1B). Parasite cells were numerous and observed systemically

Figure 1. H&E-stained histological section of *Perkinsus marinus* lesions in the gonad of *Crassostrea ariakensis*. (A) Low power photomicrograph showing the extent of the lesions (arrows) in the vicinity of the gonoduct (g). Square represents the area shown in B. (B) Higher magnification in the vicinity of a gonoduct (g) showing *P. marinus* cells (arrows) in the lesions.

throughout the visceral mass. Obvious lesions caused by *Perkinsus* sp. infection were not observed by histology in tissue sections taken from animals with light or moderate *Perkinsus* sp. tissue burdens as determined by the RFTM assays.

ISH Assay Results

In-situ hybridization probes designed to target the LSU rRNA genes of *P. marinus* or *P. olseni* exhibited specificity for the targeted *Perkinsus* species. In the specificity tests, the *P. marinus* probe hybridized only to the *Perkinsus* cells in the sample of *P. marinus* in *C. virginica* and the *P. olseni* probe hybridized to *Perkinsus* sp. cells in the control sample of *P. olseni* in *Haliotis laevis*. The probes did not cross-react with nontargeted *Perkinsus* species or host tissues in other control samples. Figure 2A to D shows four consecutive sections from the heavily infected oyster shown in Figure 1. Figure 2A is an H&E-stained section. Figure 2B shows positive *in-situ* hybridization with the PmarDIGLSU-181 probe to *Perkinsus* sp. cells indicating that the lesions were caused by *P. marinus*. The *P. marinus*-specific probe bound to cells throughout the digestive epithelium, gonads and gonoducts. *In situ* hybridization reactions conducted without probe (Fig. 2C), or with the PolsDIGLSU-464 probe (Fig. 2D), produced no signal in host tissues of this oyster. The PolsDIGLSU-464 probe was also tested against two individuals that were inoculated with *P. olseni* and found to harbor both *P. marinus* and *P. olseni* DNA by the PCR assays. The *P. marinus* probe hybridized to *Perkinsus* sp. cells in the dually infected oysters, however, no binding of the *P. olseni* probe was observed, suggesting that infections by *P. olseni* were extremely light, or that only *P. olseni* DNA was present and not viable cells.

DISCUSSION

Initial screening using a PCR-based diagnostic method on a sample of the triploid *C. ariakensis* oysters that were obtained for the challenge study suggested that they did not harbor *P. marinus*. A small sample ($n = 5$) of these oysters screened 59 days later, however, had 100% *P. marinus* DNA prevalence as indicated by the *P. marinus*-specific PCR assay. We suggest that the *C. ariakensis* oysters either acquired a small number of *P. marinus* cells that were not numerous enough to be detected by our initial PCR assay of gill/mantle tissue, while in the VIMS hatchery before collection for this experiment, or while being held in unfiltered York River water for 4 days prior to being brought into the aquaria where they were subsequently held only in filtered York River water. The *P. marinus* proliferated to PCR detectable levels after 59 days in aquaria with disease developing and mortality subsequently occurring in not only those oyster groups that had been subjected to notching and inoculation with either SASW or *P. olseni* for the challenge study, but also in the control group of unnotched and untreated oysters that were simply held for an additional 37 days during the challenge experiment.

RFTM and PCR assay results for the *C. ariakensis* initially inoculated with either 25 ppt SASW or cultured *P. olseni* cells for the challenge study revealed a progression of *P. marinus* infection in the oyster tissues. Sampling and subsequent PCR-based screening of both the 25 SASW and *P. olseni*-inoculated oysters on Days 21 and 44 indicated that *P. marinus* DNA was found in 83.3% and 66.7% of the oysters, respectively. We believe that the apparent decrease in *P. marinus* prevalence on day 44 reflects sampling error related to the small sample sizes ($n = 6$) assayed to determine PCR-based *Perkinsus* sp. prevalence at each time

Figure 2. *Perkinsus marinus* in *Crassostrea ariakensis*. (A) H&E-stained histological section in the vicinity of a gonoduct (g) showing *Perkinsus marinus* lesions (arrows). (B) *In situ* hybridization with the *P. marinus*-specific probe, Pmar181LSUDIG, illustrating strong binding to the *Perkinsus* sp. cells (arrows). (C) No probe negative control showing no binding to the *C. ariakensis* tissue. (D) *In situ* hybridization with the *P. olseni*-specific probe, Pols464LSUDIG, illustrating no binding to the *Perkinsus* sp. cells.

point. Although *P. olseni* DNA was found in two of the *P. olseni*-inoculated oysters (one each on days 21 and 72), there was an increase in the observed PCR prevalence of *P. marinus* DNA to 100% in samples of all treated oysters collected on days 59 and 72. Likewise, as determined by RFTM assays, the tissue burdens for the two positive individuals were light in the *P. olseni*-treated oysters collected on day 44 of the experiment. However, among samples of these same oyster groups that were collected on days 59 and 72, not only light infections, but also moderate to very heavy tissue burdens were observed. Interestingly, disease progression in those *C. ariakensis* not notched or inoculated, mimicked that seen in the manipulated experimental oysters based on the RFTM-based tissue burdens. By day 37 when the control oysters were sacrificed, the observed *Perkinsus* sp. tissue burdens ranged from light to moderate/heavy.

During the course of the experiment, there were many instances where dead oysters were discovered in the various treatment groups, with little or no tissue available for either PCR or RFTM analysis. It is important to note, however, that of the 1 dead oysters with available tissue, more than half (55%) had moderate to heavy tissue burdens.

Prevalence and intensity of *P. marinus* infections in *C. virginica* oysters are closely linked to temperature and salinity, and the rate of infection in the natural environment is believed to be proportional to the number of waterborne infective cells (Andrews & Hewatt 1957, Chu et al. 1994). Warm water temperatures, 20°C to 25°C, and high salinity >15 ppt, have been shown to correlate with times of maximal proliferation of parasite cells, as well as highest incidences of infection in oysters (Andrews & Hewatt 1957, Chu et al. 1994). Mortality of infected oyster hosts depends on the level of infection, with an apparent dose of between 10 and 100 cells adequate to establish infection (Chu 1996). Because of the effects of salinity and temperature on the parasite, the infections caused by *P. marinus* are seasonal in the Chesapeake Bay, with maximum parasite prevalence recorded in late summer and minimum prevalence observed during the winter months (Burrenson & Ragone Calvo 1996). York River water conditions during the time that the oysters were in the holding tank were approximately 9°C and 16 ppt salinity. Environmental conditions of the York River were not likely favorable for *P. marinus* proliferation at the start of these experiments; however, it has been shown that parasite cells can remain viable in over wintering conditions of temperatures as low as 4°C and a salinity of 4 ppt (Chu & Greene 1989, Ragone Calvo & Burrenson 1994, Chu 1996). Therefore, we cannot discount the possible presence of parasite cells in the York River water during the holding period, when the oysters were in unfiltered water. The experimental conditions under which the oysters were held, 20°C and 25 ppt salinity, would have favored the proliferation of *P. marinus* cells present in the oysters, accounting for the increase in infection prevalence observed after the baseline sampling.

Cumulative mortalities were highest in those treatments where oysters were subjected to the extra stress of notching and injection, and the highest *Perkinsus* sp. tissue burdens were seen in dead *C. ariakensis*. We may have observed higher cumulative mortalities

in the untreated control oysters, as well, had they been held for a longer time period. In *C. virginica*, digestive gland epithelia and the stomach are often heavily colonized with *P. marinus* and damaged. As parasite proliferation increases to lethal levels, massive tissue sloughing occurs, which eventually contributes to the death of the animals (Mackin, 1951). In this study, tissue sections from a moribund *C. ariakensis* with a very heavy RFTM ranking showed dense, systemic *P. marinus* infection and the ISH assays confirmed that all of the observable *Perkinsus* sp. cells were *P. marinus*. Collectively, the results presented here strongly suggest that *P. marinus* was an important contributing factor to the death of these oysters.

Because *P. olseni* was found during a recent survey of *C. ariakensis* populations in Asia (Moss & Reece 2005), this study was initiated to examine the pathogenicity of *P. olseni* to *C. ariakensis*. At the termination of this experiment, however, PCR based diagnostics suggested that a relatively low number of the *P. olseni*-inoculated *C. ariakensis* ($n = 2$) harbored both *P. marinus* and *P. olseni* DNA. This result may indicate that *C. ariakensis* are not readily susceptible to *P. olseni*, or that virulence attenuation of the parasite may have occurred during the culturing period prior to the use of the parasite as inoculum. Virulence attenuation with *in-vitro* cultured *P. marinus* cells has been documented (Ford et al. 2002). Recent studies, however, have demonstrated that cultured cell virulence is enhanced by supplementing media with host oyster homogenate (MacIntyre et al. 2003, Earnhart et al. 2004) and therefore, we plan to do homogenate supplementation of media for *Perkinsus* sp. isolates used in future challenge studies.

Although little data on *P. olseni* pathogenicity was obtained during this experiment, it provided valuable information regarding the potential for advanced *P. marinus* infections to occur in *C. ariakensis*. Prior field studies conducted in Chesapeake Bay have indicated that although *C. ariakensis* is capable of acquiring *P. marinus* infections (Calvo et al. 2001), there was no evidence that *C. ariakensis* was susceptible to the advanced parasite infections known to occur in *C. virginica*. We contend that the experimental environmental conditions, under which the oysters were held for a total of 5 months, combined with the stress of the unnatural aquaria environment and experimental manipulation, may have promoted the development of the intense *P. marinus* infections in *C. ariakensis* that were observed here. This study provides valuable information on potentially problematic disease issues including parasite proliferation that can arise if *P. marinus*-infected *C. ariakensis* encounter stress challenges in the wild or aquaculture environment, or if they are held in hatcheries or laboratories under stressful conditions.

ACKNOWLEDGMENTS

The authors thank Dr. S.K. Allen, Jr. of the Aquaculture and Genetics Breeding Center at VIMS for providing *Crassostrea ariakensis* oysters; Georgeta Constantin and Alanna MacIntyre for technical assistance in experimental set-up and Dr. Hamish Small for providing editorial assistance. AGE AND GROWTH OF WILD SUMINOE (*CRASSOSTREA ARIAKENSIS*, FUGITA 1913) AND PACIFIC (*C. GIGAS*, THUNBERG 1793) OYSTERS FROM LAIZHOU BAY, CHINA

JULIANA M. HARDING* AND ROGER MANN

Department of Fisheries Science, Virginia Institute of Marine Science, College of William and Mary,
P.O. Box 1346, Gloucester Point, Virginia 23062

ABSTRACT Shell height at age estimates from Suminoe (*Crassostrea ariakensis*) and Pacific (*C. gigas*) oysters from a natural oyster reef in Laizhou Bay, China were compared with shell height at age estimates from triploid *C. ariakensis* of known age from the Rappahannock River, Virginia. *C. ariakensis* and *C. gigas* reach shell heights in excess of 76 mm (3 inches) within 2 years after settlement regardless of the source location. This fast growth appears to continue through at least age 4 or age 5 in wild individuals, because the growth trajectories for both species had not reached asymptotic height in the oldest individuals collected. Estimates of the asymptotic maximum height (SH_{max}) from fitted Von Bertalanffy (VB) growth models were greatest for Chinese *C. ariakensis* (244.0 mm, standard error of the mean [SE] 30.4) and near the maximum shell height (227.0 mm) measured at the time of collection. Maximum shell heights measured on live Chinese *C. gigas* (173.0 mm) and Rappahannock *C. ariakensis* (190.0 mm) were also within the standard error estimates for the SH_{max} estimates from the fitted VB models for Chinese *C. gigas* (158.6 mm, SE 20.3) and Rappahannock *C. ariakensis* (183 mm, SE 19.1). Fitted VB growth curves were not significantly different between species within the same habitat, within species in different habitats or between species in different habitats. The ratio of shell height to shell width and shell height to shell inflation for triploid *C. ariakensis* was significantly less than similar ratios observed in wild *C. ariakensis* and *C. gigas* oysters.

KEY WORDS: Suminoe oyster, *Crassostrea ariakensis*, Pacific oyster, *Crassostrea gigas*, age determination, bivalves, oysters, growth rates, resilium

INTRODUCTION

Bivalves carry a complete record of their lives in their shells (Pannella & MacClintock 1968, Lutz & Rhoads 1980, Richardson 2001). Environmental changes as well as seasonal changes in biology and physiology are recorded in the shell structure as external rings, internal lines and growth increments or both (e.g., Pannella & MacClintock 1968, Lutz & Rhoads 1980, Ropes 1985, Richardson 2001). Using the terminology of Richardson (2001), a growth line is an internal line deposited once a year (annually), whereas the annual growth increment is the distance separating adjacent growth lines. In oysters, internal growth lines may be observed in the resilium of the hinge structure (Richardson et al. 1993a, 1993b, Kirby et al. 1998, Richardson 2001) and in the middle homogenous shell layers. The resilium is protected from damage or erosion by the valves. During periods of reduced shell growth, the ligament growth also slows producing growth lines in both shell and resilium (Richardson 2001). In temperate oysters, the annual growth cycle includes one thick, grey growth line deposited in between white growth increments (Richardson et al. 1993a). Enumerating the thick grey growth lines within a resilium or shell cross section provides an estimate of age (years) for the oyster (Richardson et al. 1993a, 1993b, Kirby et al. 1998, Richardson 2001).

Pacific (*Crassostrea gigas*, Thunberg 1793) oysters are cultured for commercial purposes around the world with initial introductions often made to supplement native oyster stocks (see reviews by Mann 1981, Mann et al. 1991, Shatkin et al. 1997). In recent years, Suminoe (*C. ariakensis*, Fugita 1913) oysters have also been proposed as candidates for commercial aquaculture and/or introductions to supplement native oyster stocks (e.g., Langdon & Robinson 1996, Hallerman et al. 2002). Whereas little is known about the population age structure of wild populations of either species in natural reef settings in their native Asian waters, some

data on growth rates in native waters are available. Zhang and Lou (1956, reported by Zhou & Allen 2003) report Chinese *C. ariakensis* reaching sizes of 100–160 mm shell height in 2–3 y, whereas Fujimori (1929, reported by Cahn 1950) describes Japanese *C. ariakensis* reaching 197-mm shell height at ages of 6 y; *C. ariakensis* from China and Japan are described as large reaching sizes in excess of 200 mm shell height (Torigoe 1981).

The observed morphology of these oysters is variable. The morphology of *C. ariakensis* has been described as discoid (Ahmed 1971) and oval or rounded with relatively flat shell layers with only the left valve concave (Wakiya 1929, Torigoe 1981). Wakiya (1929) describes shells of *C. ariakensis* from soft mud habitats as “extremely elongated” and difficult to distinguish from *C. gigas* found on mud bottoms. *C. gigas* are also described as large (reaching shell heights >400 mm, Torigoe 1981) but both valves are concave with rippled shell layers (Torigoe 1981, Langdon & Robinson 1996). Torigoe (1981) describes *C. gigas* as “oval to spatulate,” but Wakiya (1929) describes adult *C. gigas* as “extremely elongated”.

The objectives of this study are to describe shell morphology, shell height at age relationships and growth curves for wild *C. ariakensis* and *C. gigas* specimens collected concurrently from a natural population of reef oysters in Laizhou Bay, Gulf of Bohai, China and compare these data with shell morphology, shell height at age relationships, and growth curves for triploid *C. ariakensis* grown in Chesapeake Bay, USA.

METHODS

Sample Collection

Oysters of both species were collected from the same natural intertidal oyster reef in Laizhou Bay, Gulf of Bohai, China (37°14'38.0, 119°03'29.9) during a quadrat survey conducted in June 2004 by Dr. Mark Luckenbach (Virginia Institute of Marine Science (VIMS), Eastern Shore Laboratory) and Dr. Christopher Richardson (University of Wales Bangor, Menai Bridge). Ambient

*Corresponding author. E-mail: jharding@vims.edu

salinities were 30 ppt at the time of collection. Oyster shells were separated from meats in the field at the time of collection. Shells were labeled, bagged and shipped as valve pairs corresponding to individuals. The species co-occurred on the reef and were distinguished from each other by genetic analyses (mitochondrial 16S-based molecular key, per Banks et al. 1993) of tissue samples conducted by Dr. Ryan Carnegie (VIMS, Department of Environmental and Aquatic Animal Health). A total of 11 *C. ariakensis* individuals and 186 *C. gigas* individuals were identified from this collection on the basis of genetic analyses.

Four triploid *C. ariakensis* were collected from the lower Rappahannock River, Virginia during May 2004 as the remnant of a controlled field experiment conducted with aquacultured triploid *C. ariakensis* in 2001 (Dr. J. Wesson, Virginia Marine Resources Commission). These animals were spawned at VIMS in June 2000 (Dr. S. K. Allen, VIMS Aquaculture Genetics and Breeding Technology Center, pers. comm.); thus when they were collected and again certified as triploid in May 2004 they were approximately 4 years old.

Laboratory Methods

The hinge structure and shell morphology of each individual oyster was examined to evaluate suitability for sectioning and age estimation. Oysters in which the resilium, adductor muscle scar and growth edge on the left valve that formed a straight line were deemed suitable for aging and were set aside. A total of nine Chinese *C. ariakensis* and 19 Chinese *C. gigas* were suitable for estimation of age and growth rates. All four of the Rappahannock triploid *C. ariakensis* were used for age estimation.

The shells for estimation of age and growth rates were gently cleaned to remove attached epifauna using a sonicator. Measurements of shell height (SH, maximum dimension from the hinge to the growth edge, mm), maximum shell width (SW, maximum dimension perpendicular to the hinge across one valve, mm) and maximum shell inflation (SI, maximum dimension perpendicular to the hinge across both valves, mm) were made for each individual (Fig. 1). The ratios of (1) SH to SW and (2) SH to SI were calculated for each individual as metrics to describe shell shape. SH:SW ratios near 1 indicate a disk shaped or round individual, whereas SH:SW ratio values >2 are indicative of individuals that are long and narrow. SH:SI ratios provide an index of cupping or depth. SH:SI ratio values near 1 indicate an individual that is as deep or cupped as it is long (a spherical oyster), whereas higher SH:SI values describe oysters that are longer than they are deep. SH:SW and SH:SI ratios were compared across species within a site (Chinese *C. ariakensis* vs. Chinese *C. gigas*) and across sites within a species (Chinese vs. Rappahannock *C. ariakensis*) using 1-way ANOVAs with significance values set at $P = 0.05$ a priori.

Shells were sectioned from hinge to the growth edge along a straight line that included the resilium and adductor muscle scar (the major axis of growth, Fig. 1 (a) using a diamond blade saw. Shell cross-sections were polished using wettable carborundum disks (240 through 600 grit) and diamond polishing suspension (Buehler Metadai, 6 and 1 μ m suspension). Shells were allowed to dry thoroughly after polishing before examination for growth signatures.

The section of the left valve containing the bulk of the adductor muscle scar was used for shell cross-section evaluation. The number of growth lines within each shell cross section were counted by following the thick grey lines that were continuous from the hinge

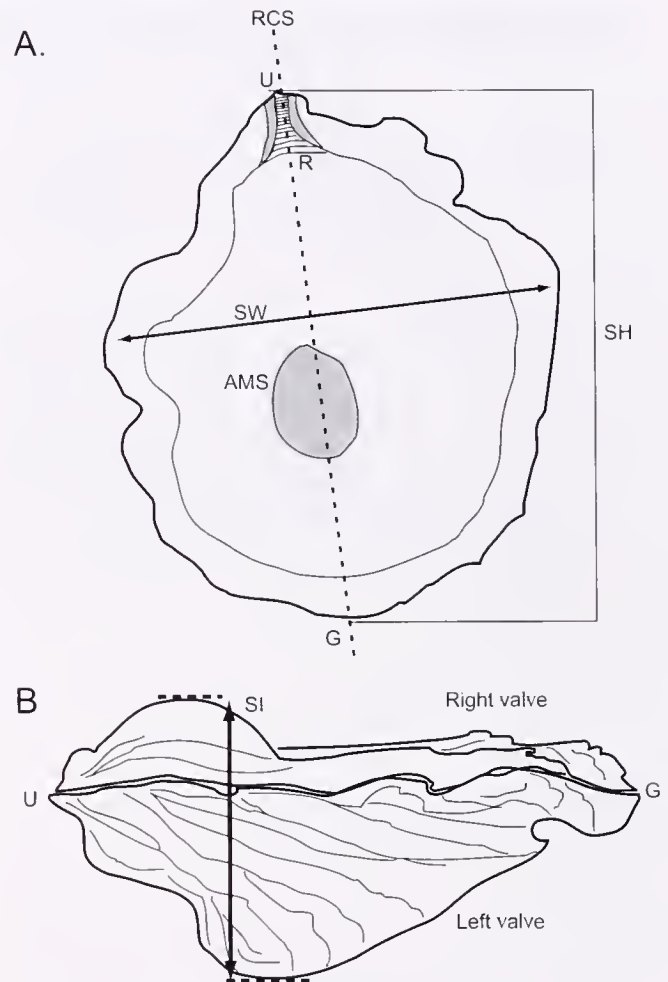

Figure 1. (A) Sketch of the left valve of a *Crassostrea* shell with the umbo (U), resilium (R), and adductor muscle scar (AMS) shown as reference points. Morphological measurements made for each shell are shown including shell height (SH, mm), shell width (SW), and shell inflation (SI). After morphological measurements were made, a radial cross section (RCS) was made for each shell following the growth trajectory through the resilium (R) and AMS to the growth edge (G). (B) Sketch of a valves of a *Crassostrea* shell in profile showing where the measurement for shell inflation (SI) was made.

to the outer shell layer throughout the valve radial cross section (Fig. 2a). Lines visible in the cross section had to also be visible in the resilium structure to be included (Fig. 2b). The position of growth lines along the radial cross section in relation to the resilium of the hinge ligament provides a growth curve for individual animals. The distance from the hinge to the emergence of a growth line in the shell exterior of the radial cross section was measured (mm) for each shell. The resilium was used to validate cross section lines given the foliation and ornamentation found in the shells of larger specimens. Shell height (mm) at age (yr) curves were plotted for populations based on the sequential measurements of growth lines (height at age) made from left valve cross sections from a size range of individuals.

Population growth curves (age (yr), shell height (mm)) were fitted using the von Bertalanffy (VB) model (von Bertalanffy 1938) with nonlinear least squares regression. This model describes maximum growth and does not assume rotational symmetry about an inflection point (Brown & Rothery 1993). It has been

Figure 2. A. Sketch of a radial cross section of a *Crassostrea* left valve showing the annual growth lines (black arrows). Shell height at age measurements were made along axis U-G from the umbo to locations where the annual growth lines ended at the periostracum (P). B. Photograph of a representative resilium radial cross section from a 2-year-old *C. gigas* with the annual growth lines marked (black arrows).

used extensively to describe the growth of other species of shellfish (e.g., *Spisula solidissima*, Sephton & Bryan 1990; *Rangia cuneata*, Fritz et al. 1990, *Mercenaria mercenaria*, Jones et al. 1990, Devillers et al. 1998, *Ostrea edulis*, Richardson et al. 1993a and *Tiostrea* (= *Ostrea*) *lunaria*, Richardson et al. 1993b). The model equation is:

$$SH_t = SH_{max} (1 - e^{-k(t-t_0)})$$

where SH_t is the shell height at time t , SH_{max} is the maximum or asymptotic shell height, t_0 is the size at time 0, and k is a rate constant.

The fitted VB growth curves for populations of Chinese *C. ariakensis*, Chinese *C. gigas*, and cultured Rappahannock *C. ariakensis* were compared as pairs using the nonlinear coincident curve method described by Haddon (2001) based on Chen et al. (1992) and Zar (1996). This method compares two curves using the analysis of the residual sum of squares to test if two or more nonlinear curves are statistically different (Haddon 2001).

RESULTS AND DISCUSSION

Morphology

C. ariakensis from the Rappahannock River were more cupped than similarly sized individuals of either species from China as indicated by inflation measurements and SH:SI ratios (Table 1, Fig. 3, Fig. 4). The triploid Rappahannock River individuals were discoid (plate-like) when viewed from above as indicated by SH:SW ratios near 1 (Table 1, Fig. 3, 4). Ratios of SH:SW and SH:SI for Rappahannock *C. ariakensis* were significantly less than the same ratios for Chinese *C. ariakensis* (ANOVAs, $DF = 1$, $F = 28.1$ (SH:SW) and $F = 8.86$ (SH:SI), $P < 0.05$). Ratios of SH:SW and SH:SI from Chinese *C. ariakensis* and *C. gigas* were similar (ANOVAs, $DF = 1$, $F = 0.73$ (SH:SW) and $F = 0.47$ (SH:SI), $P > 0.40$). Ratios from all four species and site combinations satisfied assumptions of homogeneity and normality without transformation. The wild Chinese *C. ariakensis* and *C. gigas* were typically long (SH), narrow (SW), and flatter in profile (SI) with higher SH:SW and SH:SI ratios than the Rappahannock River *C. ariakensis* (Table 1, Fig. 3, 4). The descriptions and photographs of *C. ariakensis* provided by Cahn (1950) and Torigoe (1981) from Ariake Bay, Japan are similar in terms of shape (tongue-like) and SH:SW ratio to the large Chinese *C. ariakensis* and *C. gigas* examined in this study (Table 1, Fig. 3A to F.4).

Shell Height at Age

Chinese *C. ariakensis* and *C. gigas* displayed overlap in the range of observed shell heights at age with each other and with the triploid *C. ariakensis* from the Rappahannock River, Virginia (Table 2). *C. ariakensis* and *C. gigas* reach shell heights in excess of 76 mm (3 inches) within 2 years after settlement (Table 2, Fig. 5) regardless of the source location. This fast growth appears to continue through at least Age 4 (*C. gigas*, Fig. 5) and Age 5 (*C. ariakensis*, Fig. 5) in wild individuals because the growth trajectory for both species had not begun to flatten in the oldest individuals collected (Fig. 5). The observed shell height ranges for each age class (Table 2) are within the ranges of previously published reports of shell heights at age for both species (Table 3). The triploid *C. ariakensis* in the Rappahannock River 2001 to 2004 followed a growth trajectory similar to that reported for Ariake Bay Japan by Cahn (1950, from Fujimori 1929, Fig. 5). The Rappahannock animals had not reached asymptotic shell height when they were collected in May 2004 (Fig. 5).

The observed range in shell heights at Age 1 for the Chinese oysters may be the result of differences in the timing of individual

TABLE 1.

Summary of morphological measurements made on individual wild diploid *C. gigas* and *C. ariakensis* from Laizhou Bay, China and cultured triploid *C. ariakensis* from the Rappahannock River, USA. Measurements were made for shell height (SH), shell width (SW), and shell thickness or inflation (SI) as shown in Figure 1 and explained in the text. Ranges for each measurement type (SH, SW, SI) are presented for each species by habitat with average ratio and standard error of the mean (SE) values.

Site	Species	n	SH Range (mm)	SW Range (mm)	SI Range (mm)	Average SH:SW Ratio (SE)	Average SH:SI Ratio (SE)
Laizhou Bay, China	<i>C. ariakensis</i>	9	113–227	60–135	26.3–72.0	1.79 (0.07)	4.01 (0.30)
	<i>C. gigas</i>	19	38–173	35–107	25.0–50.0	1.92 (0.09)	3.74 (0.23)
Rappahannock River, US	<i>C. ariakensis</i>	4	170–190	145–157	55.1–79.6	1.19 (0.03)	2.57 (0.23)

Figure 3. Photographs of representative specimens from China and the Rappahannock River, Virginia. A to C, Chinese *C. ariakensis*, SH = 227 mm.

recruitment. Potential differences in the timing of spawning (Perdue & Erickson 1984, Langdon & Robinson 1996) and recruitment between species may be offset by differences in the growth rates of each species at temperatures less than 25°C. Whereas recruits of both species grow faster at 25°C than at 15°C, *C. gigas* spat growth is less at 20°C than at 25°C and *C. ariakensis* spat grow as fast at 20°C as they do at 25°C (Langdon & Robinson 1996). *C. gigas* that settle early in the season may stop growing earlier than conspecific *C. ariakensis* because of differences in thermal physiology. Although *C. ariakensis* may recruit later, they are able to grow at lower temperatures than *C. gigas* and the relatively extended growing window probably offsets differences in the timing of recruitment resulting in the observed overlap in size range (*C. gigas*: 27–55 mm SH, *C. ariakensis*: 27–57 mm SH) when the first growth line (Age 1) was deposited.

VB Growth Model Coefficients and Model Fitting

Fitted VB growth curves (Fig. 6) were not significantly different between species within the same habitat (Chinese *C. gigas* vs. *C. ariakensis*, $F = 2.2$, $P = 0.10$, degrees of freedom = 71), within species in different habitats (Chinese *C. ariakensis* vs. Rappahannock *C. ariakensis*, $F = 1.13$, $P = 0.35$, $df = 45$) or between species in different habitats (Chinese *C. gigas* vs. Rappahannock *C. ariakensis*, $F = 0.93$, $P = 0.43$, $df = 55$).

Estimates of the asymptotic maximum height (SH_{max}) were greatest for Chinese *C. ariakensis* (244.0 mm, SE 30.41) and near the maximum shell height (227.0 mm) measured at the time of collection (Fig. 6, Table 4). Maximum shell heights measured on live Chinese *C. gigas* (173.0 mm) and Rappahannock *C. ariakensis* (190.0 mm) were also within the standard error estimates for the

Figure 3. D to F, Chinese *C. gigas*, SH = 165 mm.

SH_{max} estimates from the fitted VB models for Chinese *C. gigas* (158.6 mm, SE 20.25) and Rappahannock *C. ariakensis* (183 mm, SE 19.14; Table 4). The reported SH_{max} estimates for *C. ariakensis* (Table 4) are within the range of shell heights reported for *C. ariakensis* from Ariake Bay, Japan (Cahn 1950: 240 mm; Torigoe 1981: 200 mm). The SH_{max} estimates for *C. gigas* (Table 4) are smaller than the reported maximum size range for Japan (Cahn 1950: Tokoro, 400 mm; Torigoe 1981: Ariake Bay, 448 mm). The lack of representation of older age classes in the wild population and the fact that 13 out of the 19 *C. gigas* examined were 2 years old or less with only one 4 year old available resulted in dispro-

portionate representation of younger individuals and uneven sample sizes across the age distribution, which may have skewed the estimate of asymptotic height towards the smaller individuals (Fig. 5 and 6, Tables 2 and 4).

The k model parameter specifies the curvature of the fitted growth line (Gallucci & Quinn 1979) and is associated with the rate at which the organism approaches maximum size (Gallucci & Quinn 1979). Observed k values (Table 4) for *C. ariakensis* were 0.33 (Chinese, diploid) and 0.55 (Rappahannock triploid), respectively with a k value of 0.68 observed for the *C. gigas*. Coefficients of determination (R^2) for the Chinese and Rappahannock *C. ari-*

Figure 3. G to I, Chinese *C. gigas*, SH = 126 mm.

akensis were greater than or equal to 0.94 (Table 4). The *C. gigas* coefficient of determination was 0.89 and this may be reflective of the fact that most of the specimens examined (17/19) were less than 3 y old (Fig. 5, Tables 2 and 4). The relative under representation or absence of older *C. gigas* at or near asymptotic height is

reflected in the high k value (0.68) and lower coefficient of determination (0.89) relative to the *C. ariakensis* populations both of which had more balanced distribution of individuals across age classes (Fig. 5, Tables 2 and 4).

Salinities in Laizhou Bay (30 ppt) are higher than those typi-

Figure 3. J to L, Rappahannock *C. ariakensis*, SH = 180 mm.

cally observed in the lower Rappahannock River (12–15 ppt, Stroup & Lynn 1963), but both sites have salinities within the documented salinity tolerance of both species (e.g., Robinson 1992, Langdon & Robinson 1996, Almeida et al. 1997, Calvo et al. 1999, 2001, Grabowski et al. 2004). Seasonally water temperatures

in the Rappahannock River range from 4 °C to 28 °C (Stroup & Lynn 1963). Laizhou Bay probably experiences a similar annual water temperature range based on documented annual water temperature profiles from adjacent habitats (Yellow Sea, Chung et al. 1993; South Korean coastal habitats, Kang et al. 2000).

Figure 4. Average shell height (SH): shell width (SW) ratios (with standard error of the mean) in relation to average shell height: shell inflation (SI) ratios (with standard error of the mean) for wild Chinese *C. ariakensis* and *C. gigas* and triploid Rappahannock *C. ariakensis*. Ratios of SH:SW and SH:SI for Rappahannock *C. ariakensis* are significantly less than these ratios for Chinese *C. ariakensis* (ANOVAS, $P < 0.05$). Ratios of SH:SW and SH:SI are similar for both Chinese species (ANOVAS, $P > 0.05$).

Oysters have the potential to live in excess of 10 y in the absence of disease pressure, environmental degradation or human fishing pressure (Richardson et al. 1993a, 1993b). Evolutionarily life history has evolved to ensure success of the species over the course of its lifetime; that is, each individual only has to reproduce successfully once to maintain the population. Recruitment in wild populations should not necessarily be expected every year given

TABLE 2.

Observed average shell height (SH) at age (standard error of the mean) and the observed range of shell heights at age for populations of Chinese *C. gigas* (CHCg), Chinese *C. ariakensis* (CHCa), and Rappahannock *C. ariakensis* (RACa) examined in this study. Measurements were made from internal growth lines within the left valve of each individual. SE = standard error of the mean.

Population	Age	n	Average SH (mm, SE) at Age	Range of Observed SH at Age (mm)

	3	4	136.48 (5.54)	125–150
	4	4	156.20 (5.91)	140–165

NA = Not applicable.

Figure 5. Average shell height (mm, standard error of the mean) at age for wild Chinese *Crassostrea ariakensis* and *C. gigas* and triploid *C. ariakensis* from the Rappahannock River, Virginia, United States in relation to reported shell-height at age for *C. ariakensis* in Ariake Bay, Japan (Fujimori 1929 reported by Cahn 1950). *n* values for each species at age are presented to the right of each data point for Chinese and Rappahannock River animals.

the potential for interannual variability in recruitment to estuarine and marine benthic habitats (Loosanoff 1966, Powell & Cummins 1985). The observed age distribution within wild collections (11 2-y-old *C. gigas* out of 19 total, four 5-y-old *C. ariakensis* out of 9 total) indicates that we are seeing cohorts. Size variation within

a cohort may reflect time of settlement (early vs. late, see earlier), position in reef structure, or local conditions in the microhabitat in which the animal settled.

Comparisons of shell height at age and fitted growth curves present one element of comparison between oyster species within and across sites but these comparisons do not address the difference in inflation rates/cupping observed between the Rappahannock triploid *C. ariakensis* and the wild oysters of both species. The discoid, cupped Rappahannock oysters were larger in all dimensions than the Chinese oysters. When the four triploid Rappahannock *C. ariakensis* were shucked in May 2004, the meat fully filled the shell cavity with an average meat wet weight of 117.5 g (standard error of the mean, SE = 7.43 g) and average dry weight of 27.01 g (SE = 2.24 g). J. Harding, unpublished data). This effective increase in shell volume has a direct correlation to the biomass of the animal and, in diploid individuals, fecundity. In the absence of tissue weights (wet or dry) for the diploid Chinese oysters, direct comparisons of biomass within a species (triploid vs. diploid), site (*C. ariakensis* versus *C. gigas*) or within species across sites are impossible, although it is probable that biomass trends for sites and species follow the observed trends in external morphology. In the absence of detailed habitat or ecological in-

TABLE 4.

Von Bertalanffy growth model coefficients (standard error), coefficient of determination (R^2), and mean square of residual values for populations of Chinese *C. ariakensis* (CHCa), Chinese *C. gigas* (CHCg), and Rappahannock *C. ariakensis* (RACa). Residual mean square values are from the linear regression of observed versus predicted shell height (see text).

Population	Age/n	SHmax	k	t_0	R^2	Residual Mean Square

formation for either collection site (e.g., annual temperature and salinity profiles, sediment characterization, population density) it is impossible to attribute observed differences in morphology to genetic (triploid vs. diploid), habitat, or ecological factors including competition for space or resources. Application of these growth trajectories to other oyster populations and habitats must include consideration of genetics and individual morphology (biomass) as well as ambient seasonal salinity and water temperature profiles for the habitats of interest.

ACKNOWLEDGMENTS

The authors thank Mr. Kirby A. Carpenter (Potomac River Fisheries Commission) for his interest in and support of the project. Drs. Mark Luckenbach (VIMS ESL) and Christopher Richardson (University of Wales-Bangor, Menai Bridge) collected the Chinese oysters in June 2004. Dr. Ryan Carnegie (VIMS EAAH) provided genetic identification of individual Chinese oysters. Dr. James Wesson (Virginia Marine Resources Commission) and Dr. Standish K. Allen, Jr. (VIMS ABC) made the triploid Rappahannock individuals available. Ms. Karen Hudson (VIMS ABC) and Dr. Allen provided access to original literature used in Zhou and Allen (2003). Dr. Allen and Ms. Melissa Southworth (VIMS Molluscan Ecology Program) provided helpful reviews of earlier versions of this manuscript. This is Contribution Number 2725 from the Virginia Institute of Marine Science. Funding for this project was provided by Potomac River Fisheries Commission and Maryland Department of Natural Resources.

UNDERSTANDING THE SUCCESS AND FAILURE OF OYSTER POPULATIONS: CLIMATIC CYCLES AND *PERKINSUS MARINUS*

THOMAS M. SONIAT,^{1*} JOHN M. KLINCK,² ERIC N. POWELL³ AND EILEEN E. HOFMANN²

¹Department of Biological Sciences, Nicholls State University, Thibodaux, Louisiana 70310; ²Center for Coastal Physical Oceanography, Old Dominion University, Norfolk, Virginia 23529; ³Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers, The State University of New Jersey, Port Norris, New Jersey 08349

ABSTRACT *Perkinsus* (=Dermocystidium) *marinus* is a major cause of mortality in eastern oysters, *Crassostrea virginica*. Because initiation of infection and progression of disease are favored by high temperature and high salinity, we hypothesized that climatic cycles influence cycles of disease. Analyses of a 10-y time series of disease prevalence and intensity, chlorophyll *a*, suspended sediments, water temperature and salinity from a Louisiana site, using a wavelet technique, show a teleconnection between the El Niño-Southern Oscillation (ENSO) and oyster disease in the northern Gulf of Mexico. Salinity increases precede increased disease prevalence by several months. The changes in salinity that trigger changes in disease prevalence and intensity are strongly driven by ENSO events. Interannual variation is important in the initiation and intensification of disease, and salinity is the primary driving factor. The patterns in the environmental and disease time series suggest that epizootics can be initiated within 6 mo of a La Niña event, which produces increased water temperature and salinity. This relationship suggests an approach for predicting epizootics of *P. marinus* from climate models, which in turn can inform the management of oyster populations.

KEY WORDS: *Crassostrea virginica*, *Perkinsus marinus*, climate, wavelet analysis, seston

INTRODUCTION

A critical factor determining the success or failure of oyster populations is the initiation and progression of *Perkinsus* (=Dermocystidium) *marinus*, the causative agent of “Dermo” disease in eastern oysters (*Crassostrea virginica*). As a major cause of oyster mortality, *P. marinus* can control oyster population dynamics (Ray 1954, Quick & Mackin 1971), and hence the economic viability of the oyster-growing enterprise. Disease initiation and progression are favored by high temperature and high salinity (see Soniat 1996), and thus climatic cycles likely influence cycles of disease (Powell et al. 1992, 1996; Kim & Powell 1998).

Of particular importance to the oyster industry along the Gulf of Mexico is a teleconnection to the El Niño southern-oscillation (ENSO). El Niño is a disruption of the oceanic-atmospheric system of the tropical Pacific that occurs when the trade winds, which blow from east to west, relax allowing warm water to accumulate along the equator producing a reduction in upwelling of cold water in the eastern Pacific Ocean. One result of El Niño conditions is changes in the amount and pattern of rainfall, with the Gulf States being typically cooler and wetter during El Niño years. In contrast, La Niña conditions are associated with stronger trade winds and increased upwelling in the eastern tropical Pacific. During La Niña events, the Gulf States are warmer and drier (Ropelewski & Halpert 1986, Philander 1989). Kim and Powell (1998) suggested that infection intensity of *P. marinus* along the Gulf of Mexico follows the ENSO cycle; lower disease levels are associated with cooler, wetter El Niño years, whereas higher disease levels are associated with the warmer, drier La Niña years.

A major impediment to linking ENSO and Dermo disease along the Gulf of Mexico is the lack of appropriate long-term data sets. In the first study of this series (Soniat et al. 1998) we investigated the importance of what to measure and when to measure it. This study presents analyses of a 10-y time series of disease prevalence and intensity, components of the seston, and water tempera-

ture and salinity from a Louisiana site. Through the technique of wavelet analysis these time series are examined to determine interannual interactions among ENSO, water temperature and salinity, chlorophyll, suspended sediments and oyster disease. The results of the analyses are then used to determine the effects of interannual variation in climate on the initiation and progression of oyster disease.

MATERIALS AND METHODS

Environmental and Oyster Samples

Environmental variables were measured weekly and oysters were sampled monthly from February 2, 1992 to February 14, 2002 at a single semiprotected reef (29°11'11"N, 90°39'56"W, GPS) that is located between Bayou Petit Calliou and a small marsh island in Bay Tambour, Terrebonne Parish, Louisiana. Water depth at the site varied from 0.3–0.6 m.

Temperature (T) and salinity (S) at the study site were measured at weekly intervals; T was recorded to the nearest 0.1°C using a mercury thermometer, whereas S was measured to the nearest 0.5 ppt using a refractometer (Behrens 1965). Seston variables that included chlorophyll *a* (CHL), total suspended solids (TSS), particulate organic matter (POM) and particulate inorganic matter (PIM), were also measured weekly. Water was sampled from 0.3 m above the reef with a hand-operated peristaltic pump. For the determination of CHL, 25 mL of water was filtered through 25 mm Whatman GF/F glass fiber filters, extracted in 5 mL of 60:40 v:v acetone:dimethyl sulfoxide, and read on a Turner Designs Model 10 fluorometer (Shoef & Liem 1976). For the determination of TSS, POM and PIM, 100–250 mL of water (depending upon Secchi depth) was filtered through 47 mm Gelman A/E glass fiber filters. The filters and filtrate were dried for 1 h at 103°C to obtain TSS and then ashed at 550°C for 15 min to determine PIM (American Public Health Association 1971).

Oysters were collected by tonging. A subsample of 10 commercial size oysters (>75 mm) were culled, cleaned of epifauna and measured (anterior to posterior length) to the nearest mm. A

small piece of mantle tissue (about 4 mm²) was used to assay *Perkinsus marinus* (Ray 1966). Level of infection was scored using Mackin's 0-to-5 scale as modified by Craig et al. (1989). Percent infection (PI) and infection intensity (II) were determined, where

$$II = \frac{\text{sum of Mackin's disease code numbers}}{\text{number of infected oysters}}$$

Climate Data

The climate signature was represented by the El Niño 3.4 sea surface temperature index (EN) for the tropical-Pacific rectangle (5°N to 5°S, 170°W to 120°W) taken from the National Oceanic and Atmospheric Administration National Center for Environmental Prediction web site (www.cpc.ncep.noaa.gov/indices/Readme.index.htm). High values of this index coincide with El Niño conditions. The EN is available at monthly intervals and the value was assumed to apply to the middle of the month. The index was linearly interpolated to the times of the weekly observations.

Wavelet Analysis

The time series technique of wavelet analysis (Torrence & Compo 1998) was used with the disease and environmental data sets to investigate interannual relationships among ENSO, seston, water temperature and salinity, and oyster disease. Wavelet analysis has been applied to the study of tropical convection (Weng & Lau 1994), ENSO (Gu & Philander 1995), atmospheric cold fronts and temperature fluctuations (Gamage & Blumen 1993, Baliunas et al. 1997), ocean waves and turbulent flows (Farge 1992, Meyers et al. 1993, Liu 1994), tidal phenomena (Flinchem & Jay 2000), phytoplankton distribution (Machu et al. 1999), and symphonic music (Strang 1994). To our knowledge, this is the first application of wavelet analysis the study of shellfish.

Wavelet analysis resolves localized variations in the strength of a signal (i.e., the wave) within a time series. With this approach, the original time series is decomposed into a time-frequency space, which allows the dominant components (i.e., the wavelets) that make up the wave to be identified. For example, in a wavelet study, water height might be decomposed into semidiurnal/diurnal,

Figure 1. Wavelet analysis of temperature (T). a. Variation in the T time series, b. Power and periodicity of the T signal. The location of the solid line shows the periodicity of the signal, whereas its height represents the power of the signal. The dashed line to the left is the $P < 0.10$ significance level and the dashed line to the right is the $P < 0.05$ significance level. c. Variance averaged over an annual cycle, note that the annual T variation is highly significant over the time period. (The lower dashed line is the $P < 0.10$ significance level and the upper dashed line is the $P < 0.05$ significance level.) d. Variance averaged over 2–5 y, a range that encompasses the ENSO signal. Note that T is not significant when the variance is averaged over 2–5 y. The nonsignificant values at the beginning and end of the time series arise because the wavelet analysis assumes a periodic time series in which the values at each end match. For the time series used in this analysis, this assumption is violated. The peak that is produced by the mismatch results in artificial small scale variability that causes the lack of significance at the ends of the time series.

fortnightly, and seasonal (wind field) components (Flinchem & Jay 2000). Mathematical details of the wavelet technique are given in Daubechies (1992) and Torrence and Compo (1998).

A wavelet analysis was done for each variable (T, S, PI, II, EN, CHL, PIM) using two different mother wavelets (Paul & Morlet wavelets), which provide an approach for filtering the original time series. The Morlet wavelets give good frequency resolution but smear the dominant signals in the time domain. The Paul wavelets provide good time resolution but smear the signals in the frequency domain. Comparisons of the results from the two approaches showed that the Morlet wavelet provides adequate time resolution and superior frequency resolution over the results obtained with the Paul wavelet. Hence, only the results from the Morlet wavelet analyses are reported. Cross-wavelet analyses (CWA) were done on selected combinations of variables (T \times CHL, T \times S, T \times PI, T \times II, T \times EN, S \times PI, S \times II, S \times EN, PI \times II, PI \times EN, II \times EN) to determine correlations between different environmental and biologic processes, which in turn can suggest causative linkages.

RESULTS

Over the time of the field study, water temperature varied from 4.8°C to 32.2°C with a 10-y mean of 22.5°C (Fig. 1a). The power and periodicity of the temperature signal show a single significant periodicity centered at 1 y but extending across periods of 0.5–2 y. The periodicity is significant throughout the time series (Fig. 1c). Averaging the variance over 2–5 y, which includes the frequency of the occurrence of El Niño events, shows no significant signal in the temperature time series (Fig. 1d). This result indicates that water temperature at the study site is not significantly affected by El Niño conditions.

Analysis of the Niño 3.4 anomaly shows a strong El Niño signal in late 1997 and early 1998 (Fig. 2a). A moderate and extended El Niño occurred during 1992 to 1995. The energy spectrum (Fig. 2b) shows significance at periods of about 2.5–5 y. Analysis of the 2–5 y portion of the energy spectrum over the time series shows that this component is significant over essentially the entire time (Fig. 2c).

The chlorophyll *a* measured at the study site, varied from 1.2–55.4 $\mu\text{g/L}$ with a 10-y mean of 11.4 $\mu\text{g/L}$ (Fig. 3a). Chlorophyll has a strong and significant peak in the power spectrum at 1 y (Fig. 3b), similar to what was obtained for temperature. Cross wavelet analysis (CWA) between temperature and chlorophyll (Fig. 4a) shows significant coherence at periods of 1 y or less (Fig. 4b), which indicates that the two time series are significantly correlated at this time scale. Moreover, the 1-y phase curve (Fig. 4c) falls at about zero degrees indicating that temperature and chlorophyll are in phase at periods of 1-y; high temperature coincides with high chlorophyll. The temperature and chlorophyll time series also show coherence, although weaker, at 4 y, suggesting some multi-year coherence in the time series. The 4-y periodicity is not well developed in the analysis of the individual time series (Figs. 1c and 3c), confirming that the multiyear structure in the cross correlation is not a dominant signal.

Over the 10 y sampled, salinity ranged from 0.5–29.5 ppt, with a grand mean of 15.2 ppt (Fig. 5a). The power spectrum shows a significant peak in salinity at 4 y (Fig. 5b). In contrast to temperature, no strong annual periodicity exists in the salinity signal. The power spectrum shows that the 4–6 y portion is significant for most of the time series (Fig. 5c). Clearly, temperature and salinity are not operating in phase seasonally. In contrast, a salinity versus EN CWA (Fig. 6a) shows a barely significant peak at 2 y and a more significant peak at 4 y (Fig. 6b). The 4-y peak coincides with both power spectra of the primary analysis (Figs. 2b and 5b). The

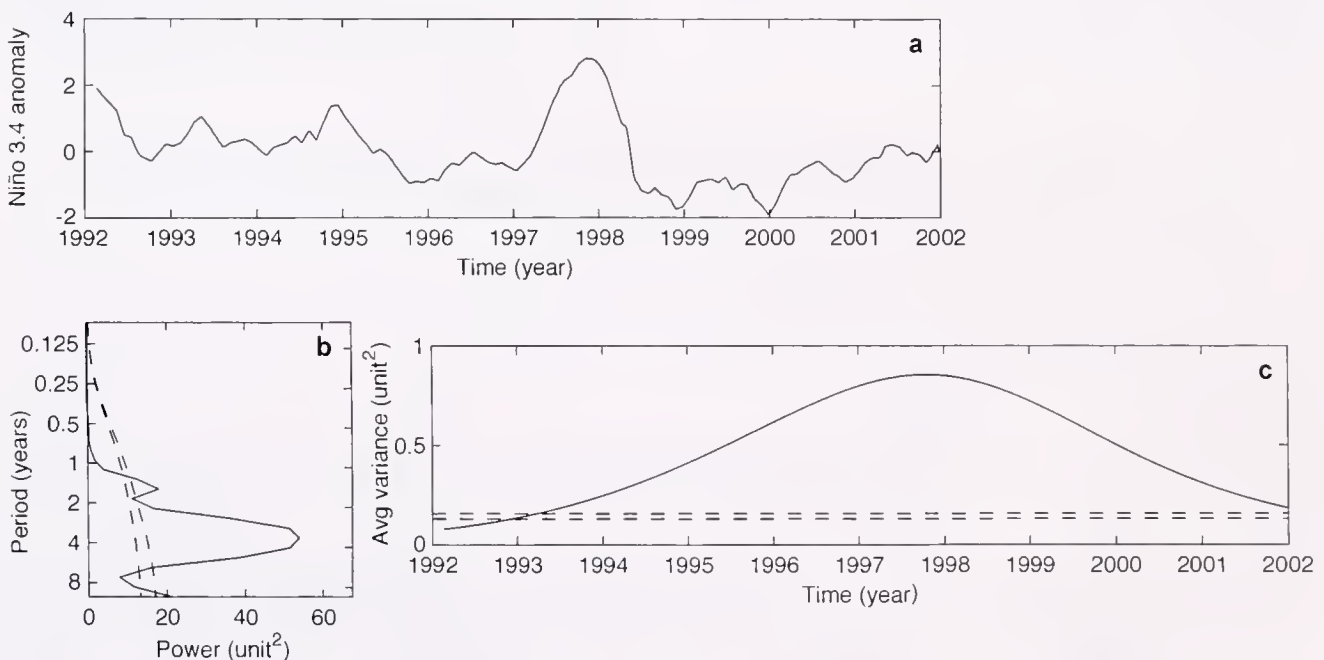

Figure 2. Wavelet analysis of the Niño 3.4 anomaly (EN). a. Variation in the EN time series. Note the strong EN signal during late 1997 and early 1998. b. Power and periodicity of the EN signal. Note the strong signal at a period of 4 y. c. Variance averaged over 2–5 y showing that EN is significant over essentially the entire time series.

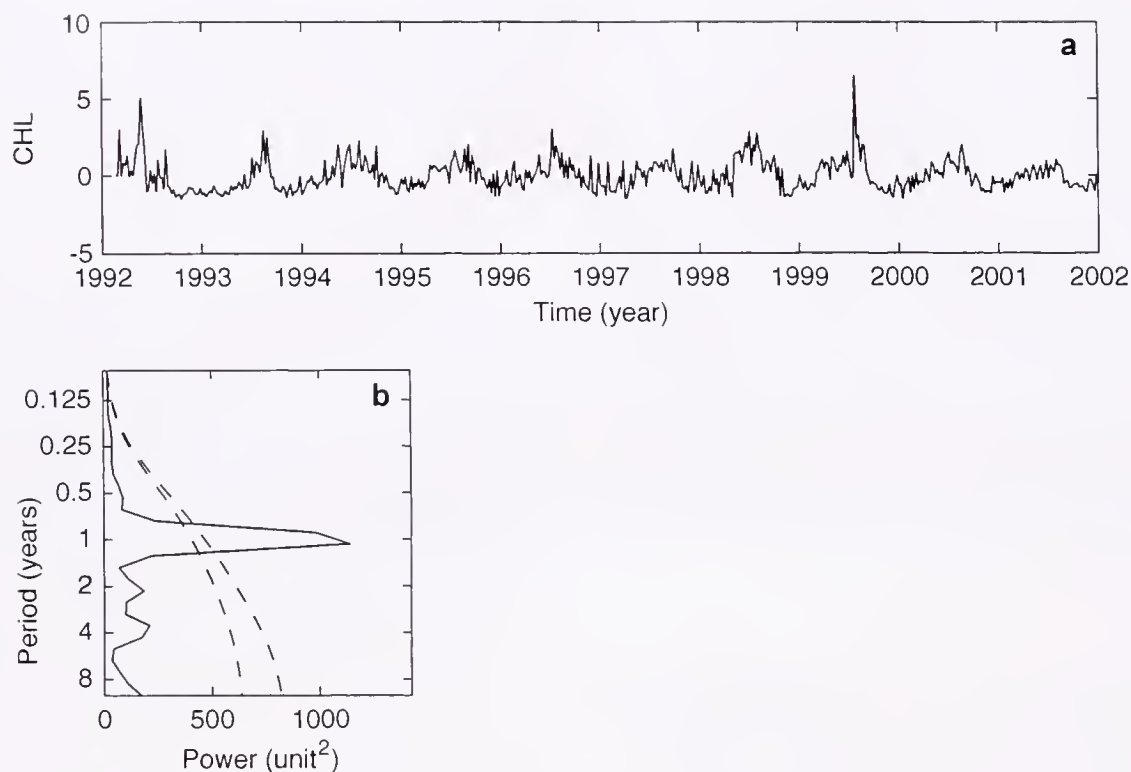

Figure 3. Wavelet analysis of chlorophyll *a* (CHL). a. Variation in the CHL time series. b. Power and periodicity of the CHL signal. Note the strong annual signal.

4-y periodicity of the two time series are roughly 180° out of phase (Fig. 6c). Thus, high salinity is associated with a low Niño 3.4 anomaly—the La Niña condition.

Particulate inorganic matter, which is a measure of resuspended sediment, varies from 4.0–531.33 mg/L with a grand mean of 50.2 mg/L (Fig. 7a). The power spectrum derived from this time series is not significant except at periods much less than 1 y (Fig. 7b),

and is not significant over the 2–5 y El Niño portion of the power spectrum (Fig. 7c).

Dermo percent infection (PI) varied from 0% to 100%, with an average of about 80% of the oysters being infected over the years sampled (Fig. 8a). The power spectrum obtained from this time series has peaks at 0.5 and 1.5 y (Fig. 8b), both of which are likely indicative of seasonal shifts in prevalence. The 0.5–2 y portion of

Figure 4. A Cross Wavelet Analysis (CWA) of chlorophyll (CHL) × temperature (T). a. Variation in the CHL and T time series. b. Power and periodicity of the CHL × T CWA. Note the strong signal at 1 y. c. Phase diagram. Note the phase of the 1-y periodicity is about 0 degrees, indicating that high T coincides with high CHL.

Figure 5. Wavelet analysis of salinity (S). a. Variation in the S time series. b. Power and periodicity of the S signal. Note the lack of an annual signal and the strong 4–6 y signal. c. Variance averaged over 4–6 y showing that S is significant over most of the time series.

the power spectrum is not significant over much of the time series (Fig. 8c), nor is the 2–5 y EN portion of the power spectrum significant (Fig. 8d).

The CWA between EN and PI, and salinity and PI show the 4-y peaks (Figs. 9b and 10b), which coincide with a peak, albeit non-significant, in the original PI spectrum (Fig. 8b). The 4-y trend in the EN \times PI CWA (Fig. 9c) is shifted by about 140° , so that high prevalence follows a low Niño 3.4 anomaly (a La-Niña high-salinity event) by about 1.5 y (phase/360 \times period or $140/360 \times 4$). The 4-y trend in salinity (Fig. 10c) is nearly in phase with the high

in prevalence. The phase shift is about -15 degrees, so high PI lags high S by about 1–2 mo.

Dermo infection intensity (II) ranged from 0.0–3.0, with an overall mean of 0.9 (Fig. 11a). The power spectrum from the Dermo II time series shows significant peaks at 0.5, 1, and 4 y (Fig. 11b). The shorter signals are subannual and annual periodicities arising from the normal seasonal progression of this disease. Averaging power in the 4–6 y period (the salinity signature, Fig. 5b) shows significance over much of the first half of the time series (Fig. 11c). Averaging power over 0.5–2 y (the temperature signal,

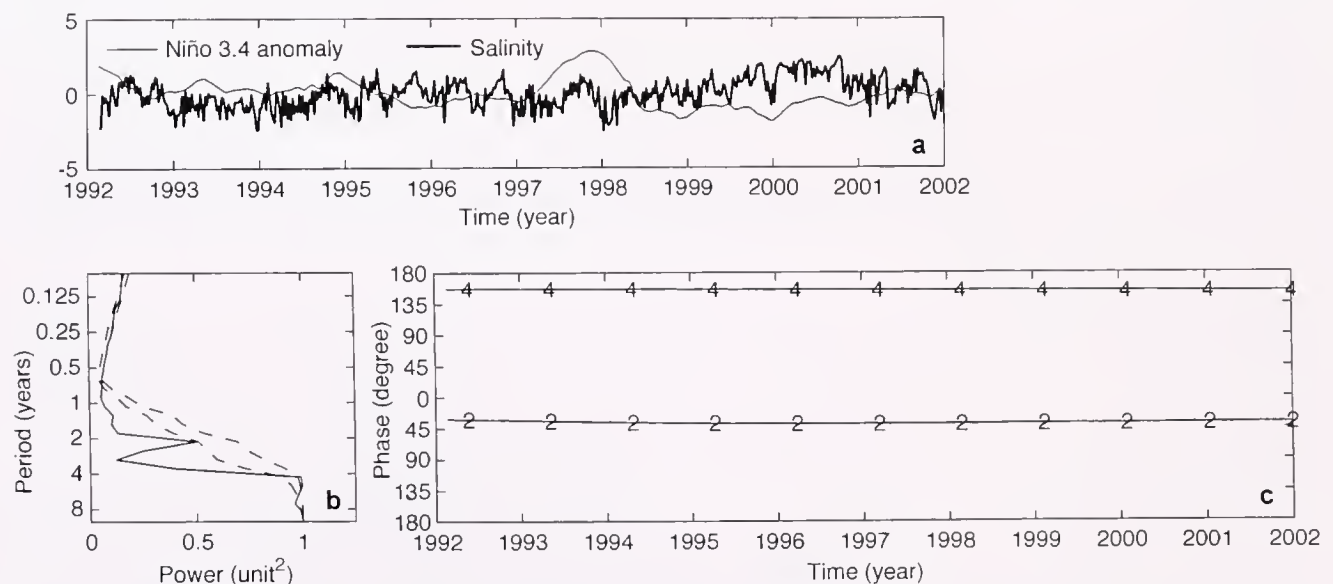

Figure 6. A CWA of the Niño 3.4 anomaly (EN) and salinity (S). a. Variation in the EN and S time series. b. Power and periodicity of the EN \times S CWA. Note the barely significant signal at 2 y and the more significant peak at 4 y. c. Phase diagram. Note that for the 4-y periodicity EN and S are nearly 180° out of phase.

Figure 7. Wavelet analysis of particulate inorganic matter (PIM). a. Variation in the PIM time series. b. Power and periodicity of the PIM signal. Note the subannual signal. c. Variance averaged over 4–6 y showing that PIM is not significant over all of the time series.

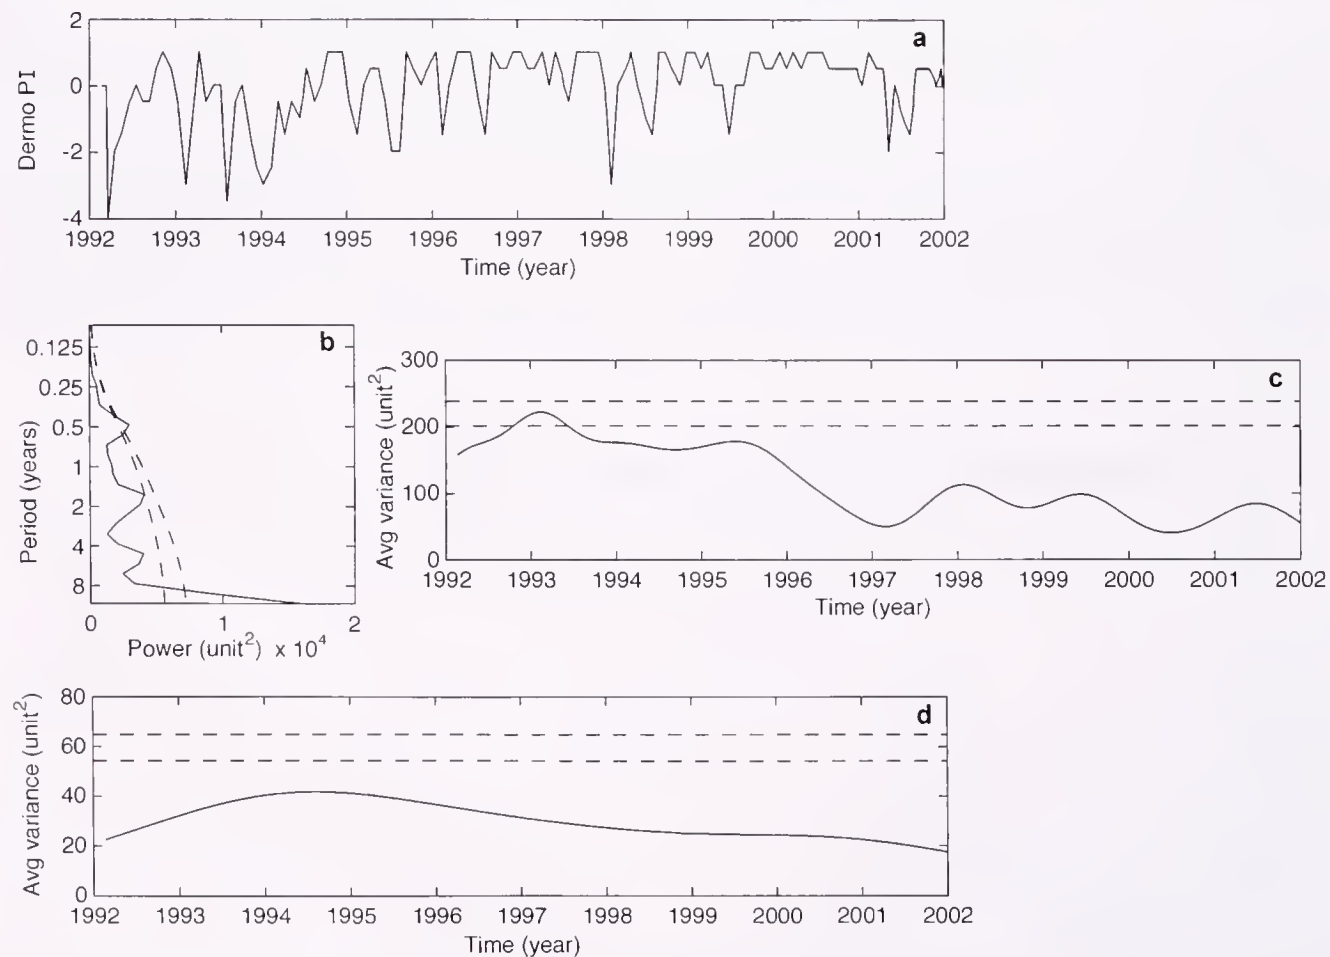

Figure 8. Wavelet analysis of Dermo percent infection (PI). a. Variation in the PI time series. b. Power and periodicity of the PI signal. Note the 0.5 and 1.5 y peaks. c. Variance averaged over 0.5–2 y showing that PI is not significant over much of the time series. d. Variance averaged over 2–5 y showing that PI is not significant over all of the time series.

Figure 9. A CWA of the Niño 3.4 anomaly (EN) and Dermo PI. a. Variation in the EN and PI time series. b. Power and periodicity of the EN \times PI CWA. Note the barely significant signal at 2 y and the more significant peak at 4 y. c. Phase diagram. Note that EN and PI are about 140 degrees out of phase.

Fig. 1b) shows a strong significant peak in the center of the time series (Fig. 11d). Averaging power over 2–5 y (the EN signature, Fig. 2b) likewise shows a strong peak in the middle of the time series (Fig. 11e). This central portion of the time series coincides with the highest infection intensities (Fig. 11a), and also with the 1996 to 1997 La Niña event (Fig. 2a).

The CWA of Dermo II and salinity (Fig. 12) shows strong and significant coherence over short periods and 4 y (Fig. 12b). The 4-y periodicity in the Dermo II time series has a phase shift of -45 degrees with respect to salinity—a phase shift of about 0.5 y. Thus, high salinity leads Dermo II by about 6 mo. The 1-y peak shows about a -30 -degree shift (Fig. 12c). This is equivalent to a -30 degrees/360 degrees \times 1 y, or 0.08 y, or about a 1 mo phase shift.

Therefore, for the 1-y periodicity, an increase in salinity precedes Dermo II by about a month. A CWA of Dermo II and EN (Fig. 13) shows a strong peak at about 3–4 y (Fig. 13b) with a phase of $+113^\circ$ (Fig. 13c), or about 1 y. That is, high Dermo II follows low Niño 3.4 anomaly values, the La Niña high-salinity event, by about 1 y.

The CWA of the Dermo PI and Dermo II time series (Fig. 14a) shows strong correlations at periods less than 1 y, at 2 y, and at 4 y (Fig. 14b). The 4-y peak has a phase shift of about -30 degrees or 0.3 y (Fig. 14c). A rise in prevalence therefore leads a rise in intensity by about 4 mo. Note that high salinity precedes high prevalence by about 2 mo (Fig. 10c), and high salinity precedes intensity by 6 mo (Fig. 12c).

Figure 10. A CWA of the salinity (S) and Dermo PI. a. Variation in the S and PI time series. b. Power and periodicity of the S \times PI CWA. Note the significant signals at 2 and 4 y. c. Phase diagram. Note that the 4 y trend in S is nearly in phase with PI.

Figure 11. Wavelet analysis of Dermo infection intensity (II). a. Variation in the II time series. b. Power and periodicity of the II signal. Note the 0.5 and 1 and 4 y peaks. c. Variance averaged over 4–6 y showing that II is significant over much of the first half of the time series. d. Variance averaged over 0.5–2 y showing a strong significant peak in the center of the time series. e. Variance averaged over 2–5 y showing a significant peak in the center of the time series.

DISCUSSION

For ENSO to exert an effect on disease levels of oysters in the northern Gulf of Mexico a number of necessary conditions must be met: (1) ENSO must have a teleconnection to weather along the Gulf, (2) weather must modify water temperature and/or salinity in local watersheds, and (3) interannual variation in ENSO must show synchrony with key environmental factors and disease levels. Ropelewski and Halpert (1986) reported an ENSO connection to the Gulf, in which El Niño years are cooler and wetter than typical years. Powell et al. (1992) found a high degree of concordance of yearly changes in disease between Gulf bays at spatial scales much

greater than 1,000 km, suggesting that PI and II are changing in response to broad shifts in weather patterns that likely directly affect local temperature and salinity (via rainfall and river runoff), and subsequently modulate PI and II.

The analyses of the time series from a site in southern Louisiana show periodicities at subannual, annual and interannual time scales. A high degree of synchrony in periodicities of measured variables with ENSO suggests interannual climatic variation as a driving force, whereas asynchrony suggests other temporal relationships such as subannual and annual control.

Particulate inorganic matter is the major component of the seston on which oysters feed. Excessive PIM can have deleterious

Figure 12. A CWA of the salinity (S) and Dermo II. a. Variation in the S and II time series. b. Power and periodicity of the $S \times II$ CWA. Note the significant subannual, annual and 4 y signals. c. Phase diagram. Note that in the 4-y trend II lags S by about 45°.

effects on oysters by “diluting” its food supply. Chlorophyll *a* is a proxy for phytoplankton biomass and represents an important component of the oyster’s food supply (Soniat et al. 1998). Particulate load and food supply are important forcing functions controlling oyster growth and Dermo prevalence and intensity (Powell et al. 1996). These also mediate assimilation by altering filtration and ingestion rates and can thus determine the success or failure of oyster populations (Soniat et al. 1998). Sub-annual periodicity is clearly seen in the PIM time series, which is a record of the resuspension of bottom sediments caused by high-frequency wind events. Temperature and chlorophyll are coupled at annual time scales through temperature control of phytoplankton growth rate. Sediment resuspension, water temperature, and chlo-

rophyll have periodicities that are not in synchrony with the EN signal and are related only to a minor degree with changes in salinity.

Unlike temperature, salinity does not show an annual signal, but instead has a 4-y periodicity like that of the EN signal. Temperature and salinity are not in phase annually, but are in phase every 4 y. Seasonal high temperature coincides during these times with high salinity, established during the La Niña portion of the ENSO cycle; high temperature and high salinity are ideal conditions for the proliferation of disease. Disease II and PI have inter-annual periodicities that suggest a connection to the EN signal.

An increase in salinity is followed in several months by an increase in prevalence followed in several months by an increase

Figure 13. A CWA of the EN and Dermo II. a. Variation in the EN and II time series. b. Power and periodicity of the $EN \times II$ CWA. Note the significant peak at 3–4 y. c. Phase diagram. Note that in the 4-y trend EN and II are about 113° out of phase.

Figure 14. A CWA of the Dermo PI and Dermo II. a. Variation in the PI and II time series. b. Power and periodicity of the PI \times II CWA. Note the subannual/annual, 2 and 4-y peaks. c. Phase diagram. Note that in the 4-y trend PI and II are about ~ 30 degrees out of phase.

in infection intensity, with salinity shifts strongly driven by ENSO events. Interannual variation is important in the initiation and intensification of disease, and salinity is the primary driving factor. This analysis of environmental and biologic time series from southern Louisiana show a teleconnection of ENSO to Dermo disease in the northern Gulf of Mexico. The correlations and phasing of signals in these time series suggest that epizootics of Dermo disease in oyster populations can be initiated within 6 mo of a La Niña event. This relationship makes it possible to potentially use results from climate models to predict epizootics of *P. marinus* in the Gulf Coast region. This provides a powerful approach for oyster management practices because it allows the possibility of an epizootic to be predicted several months in advance of the event,

which allows time for appropriate management practices to be implemented.

ACKNOWLEDGMENTS

This research was funded by the Nicholls State University Research Council and the Haskin Shellfish Research Laboratory, Rutgers University. Computer funds were provided by the Center for Coastal Physical Oceanography at Old Dominion University. Chlorophyll and seston analyses were performed in the laboratory of Mike Dagg at the Louisiana Universities Marine Consortium; Jean Rabalais provided technical assistance. Gabriel Burton helped in the preparation of the manuscript. The authors appreciate this support.

AN AFLP APPROACH TO IDENTIFY GENETIC MARKERS ASSOCIATED WITH RESISTANCE TO *VIBRIO VULNIFICUS* AND *PERKINSUS MARINUS* IN EASTERN OYSTERS

INNA M. SOKOLOVA,* JAMES D. OLIVER AND LARRY J. LEAMY

Department of Biology, University of North Carolina at Charlotte, 9201 University City Blvd., Charlotte, North Carolina 28223

ABSTRACT We conducted an arbitrary fragment length polymorphism (AFLP) analysis followed by tests of association to search for potential genetic markers associated with resistance to infection by *Vibrio vulnificus* and *Perkinsus marinus* in a sample of North Carolina oysters. We used 48 AFLP markers and found significant associations for two of these markers with the incidence of infection of *P. marinus* and two separate markers associated with the magnitude of infection of *V. vulnificus*. Further, there was evidence of epistatic interactions of genes affecting infection levels of both pathogens. This suggests existence of genes or groups of genes that are located on chromosome fragments close to the identified AFLP markers and that act directly or indirectly (through epistasis) to control the levels of infection by these microorganisms in oysters. The impact of the direct and epistatic effects of these unknown genes on infection level variability amounted to about 40% for both *P. marinus* and *V. vulnificus*. This study demonstrates the utility of the AFLP approach to identify genetic markers of pathogen/parasite resistance in eastern oysters. However, the identified AFLP markers are considered preliminary and suggestive only because of the limited sample size analyzed in this study. Further studies using this approach on a larger sample size are required to identify a set of robust molecular markers that would serve in a marker-supported breeding program designed to improve the quality of the oyster stock.

KEY WORDS: oysters, *Vibrio vulnificus*, *Perkinsus marinus*, AFLP markers, *Crassostrea virginica*

INTRODUCTION

The eastern oyster *Crassostrea virginica* (Gmelin) is an economically and ecologically important bivalve species in eastern United States estuaries that serves as a host and a vector for a variety of prokaryotic and eukaryotic parasites. Among the parasites and pathogens that have the strongest impact on the oyster industry and wild oyster populations are a bacterium, *Vibrio vulnificus*, and a protozoan, *Perkinsus marinus*. *V. vulnificus* is a human pathogen common in estuarine waters around the world, and oysters are major vectors in the transfer of this bacterium to humans. Ingestion of raw or undercooked oysters containing this bacterium can result in illness and even death (Oliver & Kaper 2003). Although this bacterium does not negatively affect oyster survival and health, it causes significant losses to the oyster industry because of the required warning labels and associated negative publicity (Keithly & Diop 2001) and is a serious concern for public health in the United States, particularly in Gulf of Mexico states. In contrast, *P. marinus* is not harmful to humans but causes devastating effects on oyster populations. Epizootics of perkinsosis or dermo disease caused by this parasite are the main source of catastrophic mortalities in oysters that can wipe out up to 100% of the living stock in affected areas, threatening both aquacultured and wild oyster populations and leading to tremendous losses in the oyster industry.

Infection levels by *V. vulnificus* and *P. marinus* in oysters are controlled by various extrinsic factors such as environmental temperature and salinity (Crosby & Roberts 1990, O'Neill et al. 1992, Chu et al. 1993, Kaspar & Tamplin 1993, Bureson & Calvo 1996, Motes et al. 1998) but these factors cannot fully explain individual variation in infection levels in oyster populations. We showed that tissue loads of *V. vulnificus* and *P. marinus* vary greatly in oysters growing in the same habitat and exposed to similar environmental conditions, including levels of pathogens in the water (Sokolova et al. 2005). This variation is likely caused by the genetic differences

in resistance to infection; in fact resistance to *P. marinus* infection in *C. virginica* was earlier shown to have a significant genetic component and to depend on the host genotype and genotype-environment interactions (Oliver & Fisher 1999, Oliver et al. 2000). Overall, genetic variation in resistance to parasites and pathogens is well documented in mollusks and thus creates a potential basis for selection of parasite-resistant populations and strains (Grosholz 1994, Bushek & Allen 1996, Naciri-Graven et al. 1998, Langand & Morand 1998, Ataev & Coustau 1999, Knight et al. 1999, Wiehn et al. 2002).

Unfortunately, selective breeding applied to oysters has met with only limited success. Currently there are several oyster lines (e.g., Andrews DEBY and their descendants) that demonstrate some resistance to dermo disease (Ford et al. 1990, Calvo et al. 2003, S. K. Allen pers. comm.). Most of these lines, however, have not proven successful in growth locations outside of their sites of origin and may also suffer from the effects of inbreeding, which limits their use in aquaculture and oyster restoration programs. Further, no oyster strains with increased resistance to *V. vulnificus* infection are currently known. On the other hand, use of molecular genetic markers associated with resistance to parasites may strongly facilitate the current selective breeding programs and provide a noninvasive tool to detect resistant oysters from wild or cultured stock. Selection of parental stock from wild or cultured populations using molecular genetic markers would avoid the negative effects of inbreeding by diversifying the genetic background of breeders, whereas selecting for the desired parasite or pathogen resistance. However, this approach has never been applied to oyster stock, and no genetic markers associated with pathogen or parasite resistance are currently known in oysters. We therefore decided to test the feasibility of an arbitrary fragment length polymorphism (AFLP) approach to search for molecular genetic markers potentially associated with resistance to *P. marinus* and/or *V. vulnificus* infections. Here we report the details of an inexpensive technique that allows identification of such markers, and provide preliminary data on associations of AFLP marker loci with resistance of *C. virginica* to both *V. vulnificus* and *P. marinus*.

MATERIALS AND METHODS

Animal Collection and Maintenance

Oysters were collected on June 15, 2004 from a subtidal habitat in Stump Sound, North Carolina. 50 adult oysters (55–155 mm valve height) were randomly collected from a small area (ca. 100 × 100 m) of homogenous soft-bottom habitat to ensure that all organisms used in this study were exposed to the same environmental conditions. Age of the oysters within this size range was 2–5 y as determined by the count of annual growth checks on their shells. Age determination by growth checks was verified by comparison with the growth checks on cultured oysters of known age grown subtidally in the nearby area of Stump Sound (courtesy of J. Swartzenberg, J & B Aquafood). Water temperature at the time of collection was 26°C and salinity was 31‰. Oysters were immediately placed on ice and transported to the University of North Carolina at Charlotte within 5 h of collection for further processing and analysis. Processing of oyster tissues was completed within 24 h of collection. During this time, oysters were kept on ice to prevent postharvest build-up of bacteria.

Chemicals

AFLP adapters and preselective and selective primers were purchased from Integrated DNA Technologies (Coralville, IA). Restriction enzymes and T4 DNA ligases were purchased from New England Biolabs (Ipswich, MA). TaqPro Complete PCR mixture was purchased from Denville Scientific (South Plainfield, NJ). All other reagents were purchased from Fisher Scientific (Sewanee, GA) and Sigma (St. Louis, MO) and were of analytical grade or higher.

Determination of *V. vulnificus* Loads and *P. marinus* Infection

Oysters were externally cleaned and opened with an alcohol-flamed oyster knife. The oyster contents were removed, weighed, and homogenized in sterile blender jars with an equal volume of sterile diluent (50% artificial sea water). Homogenates were diluted and plated for *V. vulnificus* using the cellobiose-polymyxin B-colistin (CPC) agar developed in our laboratory (Massad & Oliver 1987), which has been used by us and others for the primary isolation of *V. vulnificus* (Harwood et al. 2004, Oliver 2003). When colonies of appropriate color and morphology are selected, this medium has been shown to be 82% accurate in the isolation of *V. vulnificus* (Sun & Oliver 1995). Using these same criteria, Sloan et al. (1992) found 81% of the typical *V. vulnificus* colonies on CPC to be identified as this species.

Small samples of gill tissue (50–100 mg) were removed prior to homogenization and placed in DNA fixing solution for DNA extraction for AFLP analysis and PCR diagnostics of *P. marinus*. Remaining tissues were weighed to the nearest 0.01 g, and the maximum valve height was measured to the nearest 0.1 mm. For diagnostics of *P. marinus*, total DNA was isolated from 50–100 mg samples of gill tissue following an improved protocol for DNA isolation from mollusks developed by Sokolov (2000). This method allowed us to isolate total DNA, which in infected oysters contained DNA of *P. marinus* in addition to the host (oyster) DNA. Determination of *P. marinus* infection was performed using PCR with the following primers:

Pmar-F: 5' CAC TTG TAT TGT GAA GCA CCC 3'

Pmar-R: 5'GTG ACA TCT CCA AAT GAC C 3'

These primers are specific for *P. marinus* (Penna et al. 2001),

and do not cross-amplify with oyster DNA or other parasites. Optimized PCR conditions for *P. marinus* detection were as follows: 25 µL of reaction volume containing 1 × PCR buffer, 2 mM MgCl₂, 100 µM dNTPs, 0.7 U of *Taq* polymerase, 150 ng of each *P. marinus* primer and 50–100 ng of template DNA was subjected to one denaturation cycle at 94°C for 5 min, 35 cycles at 94°C for 45 s, 55°C for 30 s and 72°C for 45 s and one final extension cycle at 72°C for 7 min. *P. marinus* DNA obtained from monocultures of this parasite (gift of Dr. G. Vasta) was used as a positive control. Amplified DNA fragments were resolved on ethidium bromide-stained 1.5% agarose gels and screened for the presence of a ca. 304 bp product characteristic of *P. marinus*, which indicated infection of the oyster with this parasite. This method is highly sensitive with detection limits of 0.1 pg DNA of *P. marinus*, corresponding to 1 protozoan cell g⁻¹ oyster tissue (Penna et al. 2001).

AFLP Analysis

AFLP analysis was conducted according to an AFLP gene mapping protocol described elsewhere (Vos et al. 1995, Yu & Guo 2003, Li & Guo 2004). Isolated genomic DNA (~0.5–1 µg) was digested by restriction enzymes *EcoRI* and *MseI* for 1 h at 37°C. The digestion mixture (10 µL) contained 0.5–1 µg genomic DNA, 5 U *EcoRI* enzyme, 5 U *MseI* enzyme and 1 × *MseI* buffer (Buffer 2, New England Biolabs) and an appropriate amount of water. The complete digestion mixture was ligated with relevant AFLP adapters overnight at room temperature. Each ligation reaction (20 µL) contained the restriction digestion product (10 µL), 1 × T4 DNA ligase buffer with EDTA, 0.05 M NaCl, 0.05 mg mL⁻¹ BSA, 6 U T4 DNA ligase, 10-pmol *EcoRI* adapter, 100-pmol *MseI* adapter and appropriate amount of water. The structure of the *EcoRI*-adapter was:

5'-CTCGTAGACTGCGTACC
CATCTGACGCATGGTTAA-5'

The structure of the *MseI*-adapter was:

5'-GACGATGAGTCCTGAG
TACTCAGGACTCAT-5'

Ligation product was diluted 20-fold and used as a template for preselective amplification.

Preselective amplification was performed using specific primers complementary to each adaptor sequence. Each preselective PCR (20 µL) contained 10 µL of 2 × TaqPro Complete mixture with 1.5 mM MgCl₂, 100 pmol of each primer, 4 µL of 20-fold diluted ligation product and an appropriate amount of water. The cycling profile for preselective amplification was: one cycle of 72°C for 5 min to inactivate restriction and ligation, 30 cycles of 94°C for 40 s, 54°C for 40 s and 72°C for 2.5 min and one final cycle of 72°C for 10 min. Products from preselective PCR were diluted 20-fold and used as templates for selective amplifications. Pairs of selective primers complementary to each adaptor sequence (except for the last three selective nucleotides added at their 3' end) were used for selective PCR.

Each selective PCR (20 µL) contained 10 µL of 2 × TaqPro Complete mixture with 1.5 mM MgCl₂, 100 pmol of each primer, 5 µL of 20-fold diluted product of preselective amplification and appropriate amount of water. For selective PCR, a touch-down amplification was used: 10 cycles of 94°C for 20 s (denaturation), 66°C for 30 s (annealing), 72°C for 2 min (extension), with a 1°C decrease of annealing temperature each cycle, followed by 20 cycles of amplification at 94°C for 20 s, 56°C for 30 s and 72°C

for 2 min. We analyzed six combinations of primer pairs containing core sequences complementary to EcoRI or MseI adapters with addition of the following selective nucleotide triplets on 3'-end: forward primers EcoRI-ACA and -ACA, and reverse primers MseI-CTC, -CTA, and -CAG. All amplifications were performed in an Eppendorf MasterCycler Gradient thermal cycler (Brinkmann, Westbury, NY).

DNA fragments obtained by selective amplification were resolved on 8% acrylamide gels for 7–8 h in 1 × TBE buffer at 15 °C to improve resolution and were visualized by silver-staining using a method described by Sokolova and Boulding (2004). At least 3 reference samples were run on each gel as internal standards, along with 100 bp and 50 bp DNA ladders (Invitrogen, Carlsbad, CA). AFLP loci were analyzed using the Kodak EDAS 290 gel imaging system and Kodak 1D Image Analysis Software (Kodak, Rochester, NY), and scored as a presence or absence of a fragment of the respective length. Software-generated scores were verified manually. Only fragments between 100 and 350 bp were included into the analysis because shorter or longer fragments could not be reliably scored.

Originally we scored 100 AFLP markers as present or absent in a random sample of oysters, and 48 of these markers proved to be sufficiently polymorphic (neither haplotype with a frequency greater than 80%) for use. These 48 markers (designated *M1* through *M48*) were scored in 35 oysters, although 1 marker was missing in 7 oysters and 4 markers were missing in 5 oysters (all 35 markers were present in 23 of the 35 oysters). This sample of 35 contained only 3 oysters that previously had been classified as not infected with *V. vulnificus* (Sokolova et al. 2005), making the presence/absence of infection an unsuitable qualitative trait for analysis. Instead, we analyzed a quantitative trait, the magnitude of infection of *V. vulnificus* (log of CFU/g counts) among the 32 infected oysters. Because this trait was previously found to be correlated with weight of the oysters (Sokolova et al. 2005), we first used regression to adjust all these values for differences in overall weight. Our sample of 35 oysters included 7 individuals that previously were classified as not infected with *P. marinus*, making it possible to analyze association of AFLP markers with the presence/absence of infection by this parasite. Both dependent variables, the magnitude of *V. vulnificus* infection and the presence/absence of *P. marinus* infection, were tested for their association with the AFLP markers as described below.

AFLP markers are useful in a genome-wide search for gene or gene groups linked with the differential resistance to parasites or pathogens and do not require prior knowledge about the host DNA sequences; they are anonymous and thus can in principle be amplified from DNA of the host or the parasite. In this study, we used oyster gill tissues where the host DNA content is expected to exceed the parasite DNA content by several orders of magnitude because of the relatively low infection intensity (mean score 3.6 ± 0.24 by Mackin scale corresponding to medium infection, $n = 18$, Grewal & Sokolova, unpublished data) and large differences in the genome size of the host and the parasites/pathogens (700 Mb in *C. virginica* versus 28 Mb and 5.3 Mb in *P. marinus* and *V. vulnificus*, respectively) (Gregory 2001, Chen et al. 2003; <http://www.tigr.org/tldb/e2k1/pmg/intro.shtml>). Because amplification is a competitive process, the number of copies amplified from rare templates (e.g., from parasite DNA) will be negligible compared with the abundant templates (i.e., from oysters) when the same number of cycles is used, and products from rare templates are not likely to be visualized on the AFLP gel. In this study, we scored

only well-defined AFLP bands of high intensity to ensure that all AFLP markers belong to the oyster DNA.

Single-Locus Associations

As a first step in testing for associations of the marker haplotypes with infection with either *V. vulnificus* or *P. marinus*, it was necessary to assess relatedness among the 48 markers themselves. This assessment was accomplished with the MAPMAKER 3.0b program (Lander et al. 1987, Lincoln et al. 1992), which tested for potential linkage groups among these markers. We reduced the default criterion of 3.0 in this program to 2.5 to be conservative with our limited sample size, and the program identified 9 linkage groups, each with 2–4 markers. However, only 22 markers were included in these groups, with the remaining 26 being unlinked and therefore considered to be independent (effective number of total linkage groups = $9 + 22 = 31$).

We used 1-way analyses of variance (ANOVA; Sokal & Rohlf 1995) to test for associations of each of the 48 markers with the degree of *V. vulnificus* or *P. marinus* infections. In these analyses, the AFLP marker was the single factor (with two levels, presence or absence) and the degree of infection was the dependent variable. Each ANOVA yielded the conventional *F* statistic with its associated probability, with any probabilities less than 0.05 indicating conventional significance.

Because 48 ANOVAs were conducted for the analysis of *V. vulnificus* resistance, and another 48 ANOVAs for the analysis of *P. marinus* resistance, it was necessary to adjust the conventional significance level to ensure that the experiment-wise error rate did not exceed 5% (Sokal & Rohlf, 1995). To accomplish this, we used a permutation test (Churchill & Doerge 1994) involving 1,000 iterations in which the infection values (scores for *P. marinus* or *V. vulnificus*) were randomly permuted, merged with the AFLP marker data, and ANOVAs performed. These ANOVAs generated *F* values with their associated probabilities that were logarithmically transformed to produce LOD scores (Lander & Botstein 1989) as follows: $\text{LOD} = \log_{10}(1/\text{Prob})$. For each of the 31 linkage groups, the highest LOD scores generated in each permutation run were then ranked, and the 50th and 10th highest values from each distribution represented the 5% and 1% group-wise threshold LOD scores. An experiment-wise threshold value across all linkage groups also was obtained from the 50th (5%) highest LOD scores that were observed on any linkage group during each of 1000 iterations (Churchill & Doerge 1994). If the highest LOD score calculated for a given linkage group exceeded its appropriate 5% group-wise threshold value (or especially the experiment-wise value), the test of association was considered to be significant and suggested that there is a genetic locus influencing resistance to *V. vulnificus* (or *P. marinus*) infection on the chromosomal fragment adjacent to the respective AFLP marker.

Two-Locus Associations

We used 2-way ANOVAs to test for significance of pairs of AFLP markers for their potential interactive effects on *V. vulnificus* and *P. marinus* resistance and/or susceptibility. Marker pairs were tested only for the 465 pairwise combinations of the 31 linkage groups because markers within linkage groups are associated. The significance of marker epistasis was indicated by the probability associated with the *F* value for the interaction of each pair of markers in the ANOVAs.

The multiple comparisons problem inherent in this many tests

for epistasis was addressed by first calculating the effective number of independent tests for each linkage group (Cheverud 2000, Cheverud 2001). This was calculated as $M_e = M(1 - [V_\lambda(M-1)/M^2])$, where M is the number of markers scored (nonlinked markers were given an M value of 1), and V_λ is the variance of the eigenvalues of the correlation matrix of markers. The total number of independent epistasis tests then was estimated to be the sum of the crossproducts of the effective number of markers for all 465 pairs of linkage groups. This calculation yielded a sum of 814, suggesting that we might expect about $5\% \times 814 = 41$ tests to be significant at the 5% level (8 at the 1% level and 1 at the 0.1% level) because of chance alone. Thus epistasis was indicated if the number of F tests of the interactions reaching the conventional 5% level of significance significantly exceeded 41. This procedure also allowed us to test for individual instances of epistasis by correcting our threshold level of significance via the Bonferroni procedure. Specifically, any specific two-gene interaction was considered to be significant at the 10% experiment-wise level when a given probability from the F test for the interaction of markers reached the 0.1 Bonferroni threshold level of significance of $0.1/814 = 0.000123$ (Peripato et al. 2002, Leamy et al. 2005).

RESULTS

V. vulnificus Infection

Three ($M19$, $M28$ and $M31$) of the 48 AFLP markers exhibited associations with the degree of *V. vulnificus* infection that reached significance at the conventional 5% level in the ANOVAs. Further, LOD scores associated with the probabilities for two of these markers ($M28$ and $M31$) exceeded the 1% group-wise significance threshold level, although neither LOD score exceeded the 5% experiment-wise threshold value of 2.85 (Table 1). The remaining marker, $M19$, narrowly missed significance at the 5% group-wise level. Table 1 also provides means and standard errors of *V. vulnificus* infection associated with the presence/absence of each of the markers. As may be seen, alleles presumably linked to each of these markers act to increase ($M31$) or decrease ($M28$) the degree of infection.

The results of the 2-way marker analyses done to test for epistatic effects on *V. vulnificus* infection produced 64 F values with associated probabilities less than 5%, this being significantly greater than the number (41) expected at this level by chance alone ($\chi^2 = 12.99$, $df = 1$, $P < 0.001$). The number of F values reaching significance at the 1% level was 12, but this was not significantly greater than 8 expected at this level ($\chi^2 = 1.55$, $df = 1$, $P > 0.05$). One marker combination, $M42$ with $M44$, reached significance at the 10% experiment-wise level ($P = 0.000114$), suggesting that the interaction of these two markers significantly affects *V. vulnificus*

infection levels. In general, therefore, results of these analyses indicate that epistatic interactions of unknown genes linked to these AFLP markers have an effect on the infection level of *V. vulnificus* in our sample of oysters.

To assess the relative effect of individual markers and their interaction on the total variability of *V. vulnificus* infection levels, we ran two multiple regressions. A multiple regression of infection scores on the two markers ($M28$ and $M31$) reaching group-wise significance generated a multiple coefficient of determination of 27.8% (or when adjusted for the number of parameters, 22.6%). This suggests that variation in these two markers alone accounts for nearly 30% of the variation in *V. vulnificus* infection levels. Addition of the $M42$ - $M44$ significant interaction increased the amount explained to 41.8% (adjusted value = 35.4%), a significant improvement in fit ($\chi^2 = 5.77$, $P < 0.05$) from the single-locus model containing the 3 markers.

P. marinus Infection

Three markers ($M5$, $M45$ and $M47$) exhibited significance at the conventional 5% level in the tests of associations with the presence/absence of *P. marinus* infection. Two of these markers ($M5$ and $M47$) reached group-wise significance, but the remaining marker, $M45$, did not. Table 2 shows these markers, their probabilities and LOD scores, the group-wise threshold LOD scores and the percentage of *P. marinus* infection for oysters with the marker present/absent. $M5$ has the lowest probability (highest LOD score), and oysters with this marker show nearly 100% infection with *P. marinus* whereas only about one-half of those oysters without the marker are infected. As was the case for *V. vulnificus*, however, none of these markers affecting *P. marinus* reach the experiment-wise level of significance (LOD = 2.85) in the association tests. In a multiple regression, these two markers accounted for 40.0% (36.2% adjusted) of the total variation in the incidence of *P. marinus* infection.

Results of the tests for marker interactions potentially affecting the incidence of *P. marinus* infection produced 57 F values with associated probabilities less than 5%, this being significantly greater than the number (41) expected at this level by chance alone ($\chi^2 = 6.17$, $df = 1$, $P < 0.05$). The number of F values reaching significance at the 1% level was 14, and this narrowly missed being significantly greater than the 8 expected at this level ($\chi^2 = 3.81$, $df = 1$, $P > 0.05$). No marker combinations reached significance at the 10% experiment-wise level. Thus there is some suggestion of potential interactions of unknown genes affecting the incidence of *P. marinus* infection, but the evidence for this is less than was seen in the *V. vulnificus* analysis.

TABLE 1.

AFLP markers significantly associated with the degree of infection of *V. vulnificus* in the sample of oysters. Listed are the markers and their associated LOD scores, 5% and 1% group-wise threshold LOD scores, and sample sizes, means, and standard errors for *V. vulnificus* infection for the two haplotypes at each marker.

Marker	P	LOD	Threshold LOD		N	Marker present		Marker absent		
			5%	1%		Mean	St. Error	N	Mean	St. Error
$M28$	0.0114	1.94**	1.23	1.74	12	3.79	0.218	20	4.48	0.139
$M31$	0.0032	2.49**	1.62	2.24	24	4.37	0.125	7	3.62	0.355

** = $P < 0.01$

TABLE 2.

AFLP markers significantly associated with the degree of infection of *P. marinus* in the sample of oysters. Listed are the markers and their associated LOD scores, 5% and 1% group-wise threshold LOD scores, and infection percentages for oysters for which the marker is present/absent.

Marker	<i>P</i>	LOD	Threshold LOD		Marker	
			5%	1%	Present	Absent
<i>M5</i>	0.0021	2.68**	1.21	1.86	95.5%	53.9%
<i>M47</i>	0.0339	1.47*	1.36	1.81	55.5%	88.5%

* = $P < 0.05$; ** = $P < 0.01$

DISCUSSION

This study demonstrates the feasibility of the AFLP approach to search for genetic markers associated with oyster genes potentially influencing resistance to *V. vulnificus* and *P. marinus*. In fact, the results of association tests using the AFLP markers suggest that there are genes that act directly or indirectly to control the levels of infection by these parasites in oysters. We found two markers that were significantly associated with infection levels of *V. vulnificus* and two others associated with the incidence of infection of *P. marinus*. Further, there was evidence of significant genetic interactions (epistasis) affecting the levels of both pathogens, especially of *V. vulnificus*. The impact of these unknown genes on variability in infection levels was impressive, accounting for about 40% of total variation in each case.

Whereas the above-described results certainly are encouraging, they should be interpreted with caution because of the relatively small sample size used in this pilot study. This is especially so because all marker associations that reached significance were at the group-wise level, and thus may be considered only as suggestive of the presence of the linked functional genes (Lander & Kruglyak 1995) responsible for the control of infection levels. To provide significant evidence for such genes, the LOD scores should have exceeded the more conservative experiment-wise threshold level (Lander & Kruglyak 1995). Therefore, our results would need to be verified with subsequent studies using larger sample sizes as well as oysters from different populations (Kramer et al. 1998). Such verification is clearly required before AFLP markers could be recommended for use in marker-supported breeding programs aimed at selecting for resistant oyster strains. Nonetheless, even with these caveats, our results clearly imply that AFLP analysis is a viable strategy to detect such markers in oyster populations and that a future study using a larger sample size may well detect genes strongly associated with resistance to these two important parasites/pathogens in oysters.

Our results also suggest that beyond single-locus effects of genes, it is important to consider screening for epistatic interac-

tions of genes while searching for loci associated with disease/pathogen resistance in oysters. We found evidence that gene interactions affected infection levels in the oysters, especially of *V. vulnificus* where the *M42-M44* marker interaction reached experiment-wise significance in the association tests. This result involves two markers that were different from those (*M28*, *M31*) showing individually significant effects and thus would not have been detected had we conducted single-locus analyses only. This sort of result is not at all uncommon, and highlights the role of epistasis in various quantitative traits (Cheverud & Routman 1995, Leamy et al. 2002, Leamy et al. 2005), including disease resistance (Templeton 2000). Therefore, in future studies searching for genetic markers of disease resistance for marker-supported breeding programs, it seems important to take epistatic interactions between the loci into account.

As a corollary, the AFLP approach described in this study provides a cost-effective and relatively rapid method of screening of oyster stock for marker loci (or their epistatically interacting combinations) associated with resistance to two important pathogens affecting the oyster industry—*V. vulnificus* and *P. marinus*. A considerable advantage of this method is that identification of resistant oysters to be used for the parent stock can be performed noninvasively using a small tissue biopsy for DNA extraction and analysis and at a reasonable cost. We believe that the same approach may also be used with other parasites (e.g., *Haplosporidium*) or with invasive organisms such as *Polydora* providing a new tool to combat disease in oyster stocks. In host-parasite systems where the parasite genome size is small (such as in a protozoan *P. marinus* or a bacterium *V. vulnificus*) DNA isolated from the host tissue may be directly used in the AFLP analysis, especially if tissue with low to moderate infection intensity is selected ensuring that the parasite DNA content is negligible compared with the host DNA content. For parasites with large genomes or for very heavily infected tissues, it may be advisable to use markers that predominantly amplify from noninfected host individuals but not from the infected ones (such as *M47* and *M28* in this study), or to establish AFLP controls using DNA from pure parasite cultures to distinguish between the markers that are amplified from DNA of the host and the parasite.

ACKNOWLEDGMENTS

The authors thank Dr. Thomas Rosche, Ben Smith, Erin Parker and Bryn Adams for their assistance in determining the *V. vulnificus* levels; Dr. Gerardo Vasta for his gift of *P. marinus* DNA; Melanie Harrison and Danijela Bozanovic for assistance with DNA isolation and AFLP analysis; Dr. Eugene Sokolov for helpful comments on the earlier draft of the manuscript and Jim Swartzenberg of J & B Aquafood for his help with animal collection. This work was funded in part by North Carolina Sea Grant (RMG-0401), and JCSU MBRS-RISE Program NIGMS 58042. Publication costs were in part covered by the UNC Charlotte.

SEASONAL CHANGES IN DRY MASS AND ENERGETIC CONTENT OF *MUNIDA SUBRUGOSA* (CRUSTACEA: DECAPODA) IN THE BEAGLE CHANNEL, ARGENTINA

M. CAROLINA ROMERO,* GUSTAVO A. LOVRICH AND FEDERICO TAPELLA

Consejo Nacional de Investigaciones Científicas y Técnicas, CONICET, Centro Austral de Investigaciones Científicas, CADIC, CC 92, V9410BFD, Ushuaia, Tierra del Fuego, Argentina

ABSTRACT *Munida subrugosa* is the most abundant benthic species in the Beagle Channel (55°S, 68°W), Tierra del Fuego. Moreover, this species has two simultaneous but different feeding habits: predator and deposit feeder. Because of its high abundance (100 ind 100 m⁻²) and trophic position, this species plays a key role in the subantarctic benthic ecosystems. However, little is known about its energetic content and changes in dry mass during its reproductive cycle. Samples of *M. subrugosa* were obtained in 2000 to 2001 by means of an epibenthic trawl. The relative water content (WC) and the energetic content (EC) (kJ·g⁻¹ ash free dry mass [AFDM]) of whole adult animals, and the relative dry mass (RDM) and EC of tissues and organs of females were measured throughout one year. The EC investment of adults at the time of maximum gonadal development was evaluated. The EC was measured using a bomb calorimeter. The mean WC and EC for *M. subrugosa* was 59% ± 7% and 19 ± 2 kJ·g⁻¹ AFDM, respectively. WC and EC for whole adult animals varied significantly throughout the year, attaining maximum values in autumn or summer respectively, after the pattern of seasonal reproduction and feeding. Moreover, the EC of *M. subrugosa* varied by 30% annually. The RDM and EC investment in gonadal development was significant higher in females. The hepatopancreas in *M. subrugosa* is used as an energetic storage organ, because RDM and EC increased before vitellogenesis and moulting.

KEY WORDS: subantarctic, Anomura, reproductive cycle, squat lobster, *Munida gregaria*

INTRODUCTION

The anomuran crab, *Munida subrugosa* (White, 1847) attains length 5–7 cm, and nearly 15-g wet mass, that lives off southern South America, New Zealand and southern Australia (Boschi et al. 1992). In South America, the Beagle Channel represents the southern distributional limit for this species. *Munida subrugosa* constitutes up to 50% of the macrobenthic community biomass and the 85% of the density of anomuran and brachyuran decapods at the eastern entrance to (Arntz et al. 1996, Gorny et al. 1996), and in the Beagle Channel (Pérez-Barros et al. 2004). The bycatch of the hake fishery from the Atlantic shelf off Argentina during 2000 was dominated by *Munida* spp. and yielded 6674 t (Villarino et al. 2002). A second sympatric and morphological similar species, *M. gregaria* Fabricius 1973 also occurs in the Beagle Channel (Tapella et al. 2002a). The specific identity of both species is still controversial and molecular studies suggest that both are the same species probably undergoing speciation (Pérez-Barros et al. submitted). Hence, results presented in this study may be extensive and valid also for *M. gregaria*.

Currently, the only galatheids that are commercially exploited are *Pleuroncodes monodon* (H. Milne Edwards, 1837) and *Cervimunida johni* Porter, 1903 off Chile, ca. 35°S. Landings peaked 60,000 t in 1972, varied around 10,000 t during the 1980s and between 2,000 and 12,000 t during the 1990s. *Munida* spp. prospectively constitutes an exploitable shellfish at the southern tip of South America (Rayner 1935, Lovrich et al. 1998). High abundance of *Munida* spp. and its potential economical applications are comparable to those of other galatheids. Commercial uses can be as cocktail shrimp, source of natural astaxantins for coloration of cultured salmon or chicken eggs, digestive proteases for cheese manufacture, or milled as source of proteins of balanced food (Auriolles Gamboa & Balart 1995, Lovrich et al. 1998). Meat yield of *M. subrugosa* is 7.5% wet weight (Lovrich et al. 1998).

Munida subrugosa plays an important linking role in subantarctic benthic ecosystems, mainly due its trophic position (Romero

et al. 2004). In one respect as predator and deposit feeder, *M. subrugosa* feeds on lower trophic level organisms, crustaceans and algae and on detritus and sediments (Romero et al. 2004). Hence, *M. subrugosa* is responsible for incorporating organic matter into the trophic web by passing saprophytic biodegradation (Romero et al. 2004). On the other hand, *M. subrugosa*, being very abundant, is prey of several top predators. Particularly in the Beagle Channel, galateid crabs are fed on by king crabs, fishes, cormorants, penguins and whales (Romero et al. 2004). *Munida subrugosa* participates in short trophic chains, which are probably efficient in the energetic transfer, because the shorter the chain, the less energetic losses (Pianka 1982). Hence the importance of studies related to energetic contents of this species.

The study of the energetic transfer between populations is an important step in the analysis and understanding of the functioning of an ecosystem. All energy that passes through a population is either transformed to heat or to other forms of energy, or is available to pass to another trophic level. Accurate values for the energetic content of both tissues of organisms or whole organisms are essential for a better understanding of energetic relations in ecosystems. Moreover, measures of whole body energy are useful in quantifying consumption of species by their predators (Paul 1997). Hitherto, the only data for the energetic content of related species, *M. valida* Smith, 1883 and *M. iris* A. Milne Edwards, 1880, are from the deep-sea continental slope (Steimle & Terranova 1988), in the northwest Atlantic.

In decapods, bioenergetic studies of variation in energetic content during the reproductive cycle are scarce. In the shrimp *Crangon crangon* (Fabricius, 1795) a cycle of progressive and retrogressive changes between the dry mass of the ovary and hepatopancreas occurs during ovarian development (Haefner & Spaargaren 1993). Other studies report on both seasonal variations and general descriptions of the lipid content and its relation with the reproductive cycle (Clarke 1977, Teshima et al. 1989, Styris have & Andersen 2000, Wen et al. 2001, Mourente & Rodríguez 1991).

This study analyzes temporal variation in the dry mass and energetic content of *Munida subrugosa* in the Beagle Channel

*Corresponding author. E-mail: carofrau@tierradelfuego.org.ar

TABLE 1.

Predictive regression of relative dry mass (RDM) on crab size (carapace length, CL, in mm) in different sexes and ovigerous condition of *Munida subrugosa*.

Sex and Condition	Equation of Regression	CL Range (mm)	N	R ²	F	P
Non-ovigerous females	Log RDM = 2.5 log CL - 3.09	13–25	106	0.75	316.5	≤0.001
Ovigerous females	Log RDM = 2.7 log CL - 3.24	15–26	45	0.72	106.8	≤0.001
Males	Log RDM = 3.0 log CL - 3.71	16–24	151	0.78	545.4	≤0.001
	H ₀ : b _{NOF} = b _{OF} = b _M				3.5	0.031
	H ₀ : b _{NOF} = b _{OF}				0.2	0.700
	H ₀ : b _{NOF} = b _M				6.7	0.010
	H ₀ : b _{OF} = b _M				1.6	0.210

References: NOF and OF, non-ovigerous and ovigerous females, respectively. N, sample size; r² coefficient of determination. M, males; F, F-statistic.

throughout a year. The dry mass and energetic content of females and males is compared on a monthly basis. In females, the energetic changes in the ovary, hepatopancreas and abdominal muscle are analyzed on a bimonthly basis. Furthermore, the energetic investment of females and males at the maximum stage of gonadic development before mating is documented.

MATERIALS AND METHODS

Study Site and Sampling

The field work was carried out in Bahía Ushuaia, in the Beagle Channel (55° S; 68° W). Samples of *M. subrugosa* were obtained from waters shallower than 40-m depth with an epibenthic trawl net of 10-mm mesh size and 1.7-m mouth width (see Tapella 2002 for details). Crabs used for the analyses were preserved alive on-board, and dissected or frozen at -20°C on arrival at the laboratory.

The standard measure of body size, the carapace length (CL), was determined to the nearest 0.1 mm with a dial caliper. Crabs >10 mm CL are gonadal mature and therefore considered as adult individuals (Tapella et al. 2002b) as such, only crabs of >10 mm were used for this study. Average sizes for females and males used in this study were 19.9 ± 2.6 and 19.9 ± 2.4 mm CL, respectively, which is coincident with the modal sizes of the Beagle Channel population (c.f. Tapella 2002). Water content (%) and energetic content (EC) of whole *M. subrugosa* individuals, both males and females, were studied from monthly samples obtained between February and December 2000. From the total monthly catch, 12 males and 12 females were randomly selected and frozen.

The relative dry mass (RDM) and EC of different organs or tissues of female *M. subrugosa* were studied from samples taken once every second month from December 2000 to November 2001. At each sampling, 8–22 females were randomly selected from the total catch for analysis. Animals were kept in tanks with running seawater for a few hours until the dissection, then the carapace was removed, and ovaries, hepatopancreas and abdominal muscle were dissected.

To compare the energetic investment in reproduction in males and females, an additional sample of 15 male *M. subrugosa* was taken in May of 2001, when gonadosomatic indexes are near to reach their maximal values (Tapella et al. 2002b). Both testicles and vasa deferentia were used for the energetic measurements.

Water Content and Dry Mass Determination

Wet mass (WM) of the whole animals, stomach contents, hepatopancreas, abdominal muscles and ovaries of females, and testicles and vasa deferentia in males were recorded to 0.0001 g

precision. Samples were dried to constant weight at 60°C, and the dry mass (DM) recorded.

The percentage water content of the animals was calculated as (WM-DM)/WM · 100. Because the DM is dependent on the animal size, we calculated the RDM of organs and tissues, which was the DM_{organ} standardized by the DM_{whole animal}. The RDM of all animals was calculated from the animal size (CL) and according to their sex and ovigerous condition. Lineal regressions between log RDM and log CL were calculated from a different sample of several nonovigerous females, ovigerous females and males (Table 1), obtained in July and December of 2001. The equality of the slopes was checked with an analysis of covariance (Sokal & Rohlf 1995).

Calorimetric Determination

After obtaining the DM, samples were ground and pelletized with a press model Parr 2812. The caloric content of each sample was obtained by burning pellets of 20–200 mg in a calorimeter Parr model 1425 with a microbomb Parr model 1341. Energy values were calculated using standard equations (Parr Instrument Co. 1991, 1993). The values obtained were corrected for ash and acid content and were expressed as kJ·g⁻¹ ash free dry mass (AFDM). Benzoic acid calibrations were done periodically.

RESULTS

The ingestion in *Munida subrugosa* was clearly seasonal, being maximum in December (Fig. 1; ANOVA F = 25.4, P < 0.001).

Figure 1. Average monthly temperatures of the Beagle Channel (T°C) and average quantity of food (EW, mg_{ingested}·g_{animal}⁻¹) in the stomach contents of adult *Munida subrugosa*. Temperatures are historical monthly averages of the sea surface temperature, 1985 to 1998 (Balestrini et al. 1998).

Food uptake in *M. subrugosa* follows the same pattern as surface water temperature (Fig. 1: $r = 0.66$, $P = 0.02$): in autumn and winter, ingestion was almost 4 times less than in spring or summer.

For the whole adult animals values of water content and EC of male and female *M. subrugosa* varied significantly throughout the year (Fig. 2, Table 2). Overall, the mean water content and EC for both sexes were $59\% \pm 7\%$ and $19 \pm 2 \text{ kJ} \cdot \text{g}^{-1}$, respectively. The minimum and maximum values of water content were registered in autumn and winter, respectively (Fig. 2A). The minimum of EC was recorded in winter (Fig. 2B). The interaction between month and sex for the water content was statistically significant (Table 2). Particularly, the water content of females was the lowest in June (ANOVA $F = 6.24$, $P = 0.01$).

RDM and EC in Organs and Tissues

Ovaries

The ovarian RDM and EC varied significantly throughout the year (Fig. 3, Table 3). Both RDM and EC reached their maximum values in May: afterwards, RDM and EC gently decreased and in November attained values similar to December (Fig. 3).

Hepatopancreas

The hepatopancreas RDM and EC varied significantly throughout the year (Fig. 3, Table 3). RDM and EC showed two maximum values around $140 \pm 40 \text{ mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$ and $32 \pm 2 \text{ kJ} \cdot \text{g}^{-1}$, respectively, in March and November (Fig. 3). No significant differences in RDM and EC between these months were found (Tukey test, $P = 0.33$ and $P = 0.99$ for RDM and EC, respectively).

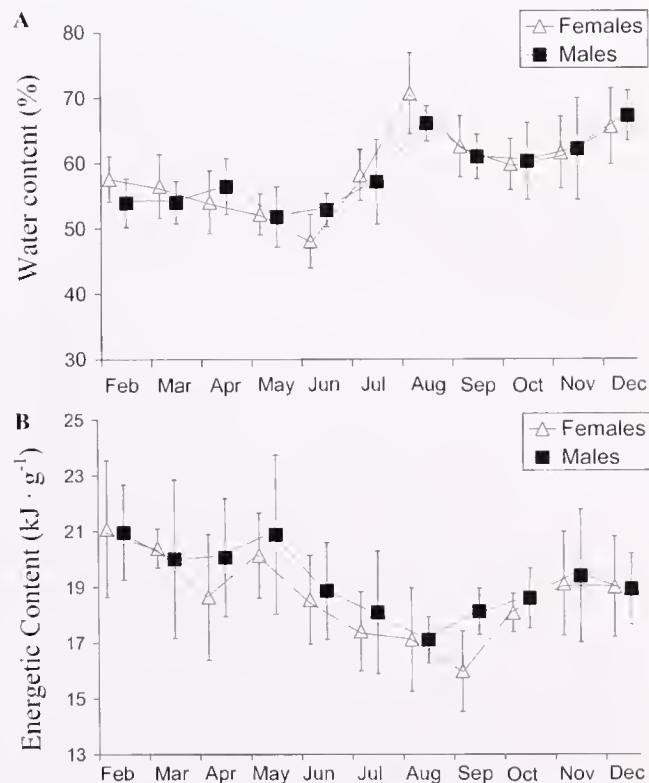

Figure 2. Mean monthly percentage of water content (\pm SD) (A) and energetic content ($\text{kJ} \cdot \text{g}^{-1}$ AFDM) (\pm SD) (B) of adult *Munida subrugosa* from the Beagle Channel between February and December 2000. Monthly sample size was 12 females and 12 males.

TABLE 2.

Two-way analyses of variance (ANOVA) to detect differences in percentage of water content and energetic content ($\text{kJ} \cdot \text{g}^{-1}$) in adult *Munida subrugosa* between sexes and throughout the year.

Source	Water Content (%)			Energetic Content		
	d.f.	MS	F	d.f.	MS	F
Month	10	776.36	35.5*	10	41.63	12.66*
Sex	1	10.43	0.5	1	16.65	5.06*
Month \times sex	10	45.53	2.1*	10	3.30	1.01
Error	242	21.87		242	3.29	

References: MS, mean square; EC, energetic content; F, F-statistic. Significant differences ($P < 0.05$) are indicated by asterisk.

Abdominal Muscle

The abdominal muscle RDM varied significantly throughout the year (Fig. 3, Table 3), principally because of a single maximum RDM recorded in March ($80 \pm 10 \text{ mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$). This value duplicated the others recorded during the study period. The EC of the abdominal muscle was similar throughout the year (Fig. 3, Table 2), with an annual mean EC of $22 \pm 2 \text{ kJ} \cdot \text{g}^{-1}$.

Relationship Among Ovary, Hepatopancreas and Abdominal Muscle

Maxima in RDM of hepatopancreas and muscle and in EC of the hepatopancreas preceded that of the ovary (Fig. 3). In terms of

Figure 3. Mean relative dry mass ($\text{mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$) (\pm SD) (A) and energetic content ($\text{kJ} \cdot \text{g}^{-1}$ AFDM) (\pm SD) (B) of ovaries, hepatopancreas and abdominal muscles of females *Munida subrugosa* from Beagle Channel between December of 2000 and November of 2001. Note that each month symbols are apart to avoid overlapping (sampling was done on the same date). Numbers on top of each point are samples sizes.

TABLE 3.

One-way analysis of variance (ANOVA) to detect differences in relative dry mass ($\text{mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$) (RDM) and energetic content ($\text{kJ} \cdot \text{g}^{-1}$ AFDM) (EC) of three different tissues of female *Munida subrugosa* throughout the year.

Source	Relative Dry Mass			Energetic Content		
	d.f.	MS	F	d.f.	MS	F
Ovary	6	3,345.51	114.02*	6	29.52	10.70*
Error	102	29.34		55	2.76	
Hepatopancreas	6	32,192.20	36.47*	6	150.07	29.91*
Error	102	882.63		91	5.02	
Abd. muscle	6	2,193.30	22.36*	6	3.09	1.19
Error	102	98.08		89	2.59	

References: Abd. muscle, abdominal muscle; F, F-statistic. Significant differences ($P < 0.05$) are indicated by asterisk.

RDM, the hepatopancreas and muscle were positive and significantly correlated (partial correlation, $r_{\text{H-M}} = 0.82$, $n = 109$, $P < 0.05$). However, in terms of EC the hepatopancreas and muscle were uncorrelated (partial correlation, $r_{\text{H-M}} = 0.088$, $n = 59$, $P > 0.05$). Hepatopancreas and ovary RDM were positive and significantly correlated (partial correlation, $r_{\text{H-O}} = 0.55$, $n = 109$, $P < 0.05$), whereas the EC of these organs was positive but not significantly correlated (partial correlation, $r_{\text{H-O}} = 0.178$, $n = 109$, $P > 0.05$). Ovary and muscle RDM and EC were negatively correlated, and none of these correlations were significant (partial correlation, $r_{\text{O-M}} = -0.31$, $n = 109$, and $r_{\text{O-M}} = -0.184$, $n = 59$, both $P > 0.05$, respectively).

Gonad Energy and Mass at the End of the Gonadal Development

The gonad RDM was significantly higher in females ($40 \pm 10 \text{ mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$) than in males ($6 \pm 2 \text{ mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$) (Student $t = 12.91$, $P < 0.001$). The gonad EC was also significantly higher in females ($26 \pm 2 \text{ kJ} \cdot \text{g}^{-1}$) than in males ($22 \pm 2 \text{ kJ} \cdot \text{g}^{-1}$) (Student $t = 4.20$, $P = 0.002$). Hepatopancreatic RDM ($80 \pm 28 \text{ mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$) and EC ($30 \pm 3 \text{ kJ} \cdot \text{g}^{-1}$) were similar in both sexes (Student $t = 0.22$, $P = 0.82$, and $t = -1.07$, $P = 0.30$, respectively). Similarly, muscle RDM ($50 \pm 9 \text{ mg}_{\text{org}} \cdot \text{g}_{\text{animal}}^{-1}$) and EC ($21 \pm 2 \text{ kJ} \cdot \text{g}^{-1}$) were also similar in both sexes (Student $t = -0.08$, $P = 0.93$ and $t = 0.56$, $P = 0.58$, respectively).

DISCUSSION

Our results depict a typical annual energetic cycle of a decapod in subantarctic latitudes (Thatje 2004 and references therein). Over the year, variations in energetic content can be divided into three different periods. During summer and autumn, the total energetic content is fairly constant (Fig. 2B), yet with a high flow of matter and energy from the hepatopancreas and muscle towards ovaries (Fig. 3B). Growth of the ovary is indicated by a maximum RDM and EC in May (Fig. 3A), which coincides with the lowest water content in the whole individuals (Fig. 2A). Subsequently during winter, the total energy content decreases after the egg-extrusion (c.f. Tapella et al. 2002b), and is coincident with a period of low ingestion (Fig. 1) and the lowest values of energy and mass in organs and tissues (Fig. 3). Finally, the energy accumulation phase occurs during the spring (Fig. 3B), when the food intake increases (Fig. 1), and the hepatopancreas grows for a second time in the

year (Fig. 3). We attribute these variations to a seasonal feeding pattern and ultimately to physiological events such as reproduction.

The seasonal variations in somatic energetic content of *M. subrugosa* probably reflect its temporal feeding patterns. Development and physiological events in ectotherms from high latitudes may be regulated by the seasonal availability of food, and the degree of food dependence given their position in the food web (Clarke 1988). Particularly, the environment of the Beagle Channel is subantarctic with a marked seasonality in surface temperature (4.5°C – 9°C in August and January, respectively) and photoperiod (18:6 light:dark in summer and *vice versa*). *Munida subrugosa* feeds on small macroalgae, small crustaceans and particulate organic matter (Romero et al. 2004). Food uptake in *M. subrugosa* follows the same pattern as water temperature. In turn, this could also reflect the different seasonal availability of producers (macroalgae and phytoplankton) and other prey with an annual life span.

In female *Munida subrugosa* maximum somatic energetic values recorded between February and May can be related to the reproductive cycle. In February, oocytes begin their secondary vitellogenesis (i.e., yolk accumulation) (Tapella et al. 2002b). This coincides first, with an increase in EC and RDM of the hepatopancreas in February and March and second with the increase in ovary EC during March and May. The ovary RDM drastically drops in July, right after the egg extrusion in June (Tapella et al. 2002b). Furthermore, the ovary EC gently decreases after egg extrusion, probably because of the presence of nonextruded oocytes and the reorganization of nutritional material associated with vitellogenesis (c.f. Johnson 1980).

The water content of *M. subrugosa* presents two maxima, in August and December. The latter is coincident with one of the peaks in RDM and EC of the hepatopancreas. These changes can be attributed to the moulting period. Tapella (2002) showed that *M. subrugosa* >10 mm CL has 2 periods of moult during the year, in spring and in summer. At moulting, decapods absorb a great quantity of water, which is later replaced by the organic matter that constitutes tissues (Vernet & Charmantier-Daures 1994). Nevertheless, the hepatopancreatic energetic increase during February is probably associated with the energy gained for summer moulting and ovarian growth.

Munida subrugosa uses its hepatopancreas to store energy, because this organ increases its RDM and EC before vitellogenesis (peaking in March) and moulting (peaking in November). Flexibility in storage and mobilization of nutrient reserves confers an evolutionary advantage, enabling an organism to stay active during periods of starvation (Crawford 1979), such as the moulting period (O'Halloran & O'Dor 1988). In crustaceans, the hepatopancreas is the principal energy supplier, and a large part of this energy is stored as lipids (e.g., Chapelle 1977, Mourente & Rodríguez 1991, Albessard et al. 2001, Ravid et al. 1999). The main functions of these stored lipids are as reserves for vitellogenesis and moulting (Dall 1981). The material accumulated by the hepatopancreas is converted to other compounds that are released into the hemolymph for an eventual use by the ovary (Haefner & Spaargaren 1993). In high latitude species, the energy stored in the hepatopancreas may be also used during winter when less food is available (Styrishave & Andersen 2000); this holds true for *M. subrugosa*, where reduced food consumption during winter (Fig. 1) is accompanied by the utilization of energy stored in the

hepatopancreas (Fig. 3B) and a general decline in its energetic content (Fig. 2B).

Somatic energetic values of *Munida subrugosa* in the Beagle Channel compare with those of other related species and benthic crustaceans in general. During summer, spring and autumn, somatic EC of *M. subrugosa* was 20.6, 18.9 and 19.5 kJ·g⁻¹, respectively. These values are similar to other galatheids from the continental slope of the northwest Atlantic. *Munida valida* presents values of 19.9 kJ·g⁻¹ in summer; *M. iris* has 19.0 kJ·g⁻¹ in spring, and *Eumunida picta* Smith 1883, has 20.6 kJ·g⁻¹ in autumn (Steimle & Terranova 1988). The mean EC for *M. subrugosa* from the Beagle Channel was 18.9 ± 1.4 kJ·g⁻¹, similar to the decapod value from the English Channel of 20.5 ± 1.5 kJ·g⁻¹ (Dauvin & Joncourt 1989) but significantly lower than the reported EC of 22.7 kJ·g⁻¹ for benthic crustaceans and the general somatic EC of 23 kJ·g⁻¹ for macrobenthic invertebrates (Brey et al. 1988).

The somatic EC of *M. subrugosa* varies throughout the year between 16 and 21 kJ·g⁻¹. Hence, calculations of consumption rates of predators should consider these seasonal variations carefully. Similarly, studies on energetic budgets of prey of *M. subrugosa* should take into account such seasonal variations. *Munida subrugosa* is one of the main prey of about 30 species of top predators in the Southwestern Atlantic (Romero et al. 2004). In the Straits of Magellan and its channel system, the density of *M. subrugosa* is as high as 27 individuals·m⁻² (Gutt et al. 1999). The Beagle Channel presents the highest biomass and productivity of macrozoobenthos of the Magellanic Region (Thatje & Mutschke 1999). Particularly at <40 m depth, the biomass of *M. subrugosa* is on average 3.4 g·m⁻² (Tapella et al. 2002a), which implies 64 kJ·m⁻² of energy easily accessible to predators above

the sea-bottom. This characteristic is important from an ecological point of view, because *Munida* spp. are part of numerous trophic chains; for example, in the Beagle Channel food consumption among populations of nine seabird species is high, and estimated to be between 1.71 and 3.42 t·d⁻¹ (Raya Rey & Schiavini 2001). Hence, *M. subrugosa* probably contribute a large proportion of the high energetic flow towards the seabirds, especially diving species like penguins and cormorants. A contrasting potential prey species in the same location is the clam *Eurhomalea exalbida* (Chemnitz, 1795), which lives buried 20 cm in the substrate and is very abundant. Patches of this clam have an average abundance of 83 ind·m⁻² and an annual biomass of 186.4 g·m⁻² (Lomovasky et al. 2002), which represents 3914.4 kJ·m⁻², 60-fold that of *M. subrugosa*. *Eurhomalea exalbida* is a filter feeder that consumes particulate organic matter. This food is converted into clam tissue and retained under the sea bottom and is unavailable to predators. This clam is a long-lived species, with a life-span of 70 y (Lomovasky et al. 2002). Animals with such life-strategies capture and retain nutrients in living tissue for decades, so that energy transfer to other trophic levels is very low compared with *Munida* spp.

THE INTERACTION OF SALINITY AND NA/K RATIO IN SEAWATER ON GROWTH, NUTRIENT RETENTION AND FOOD CONVERSION OF JUVENILE *LITOPENAEUS VANNAMEI*

CHANG-BO ZHU,^{1,2} SHUANG-LIN DONG^{1*} AND FANG WANG¹

¹Mariculture Research Laboratory, Fisheries College, Ocean University of China, Qingdao, 266003, China; ²Aquaculture and Biotechnology Division, South China Sea Fisheries Research Institute, Chinese Academy of Fishery Sciences, Guangzhou, 510300, China

ABSTRACT The effects of salinity, Na/K ratio and their interaction on growth, molting, nutrient retention and food conversion of *Litopenaeus vannamei* were investigated. The test shrimp were reared in artificial seawater and fed fresh polychaete worms, *Neanthes japonica* (Izuka) for 30 days. Two salinities (30 and 15 ppt) and 5 Na/K ratios (25.6, 34.1, 47.3, 102.1 and 153.3, mmol/mmol) were set, and each treatment had four replicates. During the feeding trial, the molting frequency (MF) was affected by neither salinity nor interaction effects, but Na/K ratio had an effect ($P < 0.05$). And there was a tendency that MF rose with the increment of Na/K ratio at both salinities. Final body weight, weight gain (WG) and specific growth rate (SGR) were significantly influenced by salinity, Na/K ratio and interaction effects ($P < 0.05$), whose mean values at salinity 15 ppt were significantly higher than those at 30 ppt. At 30 ppt, WGs and SGRs of shrimp exposed to Na/K ratio 34.1 and 47.3 were respectively more than 26% and 15% higher than of those exposed to the other ratios ($P < 0.05$), but no significant differences in growth were found among treatments at 15 ppt ($P > 0.05$). Na/K ratio and interaction effects significantly affected the nutrient retention (PR and ER), food conversion (FCE) and protein utility (PER) of the shrimp ($P < 0.05$), whereas salinity showed little impact. At 30 ppt, the PR and ER of shrimp exposed to Na/K ratio 153.3 were more than 30% lower than of those exposed to the other 4 ratios ($P < 0.05$); the FCEs of shrimp exposed to Na/K ratio 34.1 and 47.3 were more than 20% higher than of those exposed to Na/K ratio 25.6 and 102.1 ($P < 0.05$), and the FCE of shrimp exposed to Na/K ratio 153.3 was even lower ($P < 0.05$). At 15 ppt, no significant differences in FCE among treatments were found ($P > 0.05$). PER showed the similar tendency as FCE at both salinities. It was indicated that the shrimp were more adaptable to abnormal Na/K ratios at low salinity than at higher salinities, and good growth could always be obtained within a Na/K range of 34.1–47.3 (mmol/mmol) regardless of salinity.

KEY WORDS: salinity, Na/K ratio, interaction, *Litopenaeus vannamei*, growth

INTRODUCTION

Inland production of shrimp using water from saline aquifers is providing an alternative to traditional coastal aquaculture and a diversification of agriculture, and it is currently undertaken in the United States, Ecuador, Brazil, China and several other countries (Boyd 2002, McGraw et al. 2002). Until the year 2003, inland shrimp farming was present in 25 of the 31 Chinese provinces and autonomous regions, and the annual production of *L. vannamei* cultured in inland has amounted to 296,300 tons in China (Liu et al. 2004).

Although the shrimp farming technology in seawater has reached a high level, it could not be introduced to inland saline water culture directly. Comparative to seawater, the ion profile has changed a lot, and the rule of constancy of composition of seawater does not apply to inland saline water. Furthermore, the ionic composition and salinity of ground water among places can vary markedly; the natural saline water resources in many inland places could not be used in shrimp culture directly (Boyd 2002, Davis et al. 2002, Saoud et al. 2003). For example, In the saline-alkaline area of Yellow River Delta in China, the saline ground waters are chloride type, salinity varies between 5–15 ppt and most of their chemical compositions are similar to that of oceanic seawater of the same salinity except potassium, which is 90% to 95% less than similar salinity oceanic seawater, and shrimp could not survive (Wang et al. 2001, Li et al. 2002).

Current data suggests that salinity and proper ionic composition of saline water are the two necessities for culture suitability evaluations. Numerous reports focus on effects of salinity on shrimp culture (Dalla Via 1986a, 1986b, Huang 1983, Bartlett et al. 1990,

Bray et al. 1994, Vinod et al. 1996, Chen et al. 1996, Ponce-Palafox et al. 1997, Rosas et al. 2001). More studies have begun concerning the ionic imbalance of saline water, especially on supplementing potassium into potassium deficient saline water for shrimp and marine fish culture (Liu 2001, Fielder et al. 2001, Allan & Fielder 2002, McGraw & Scarpa 2003). In addition, Forsberg et al. (1996) reported that the survival of red drum *Sciaenops ocellatus* was significantly corrected with the Na/K and K/Cl ratios of the saline ground water. Zhu et al. (2004) did special experimental work on the effects of Na/K ratio in seawater on growth and energy budget of juvenile *L. vannamei*, and they found that Na/K ratio had significant effects on the survival, molting, growth and energy budget of the shrimp at salinity 30 ppt. However, salinity fluctuation and ionic imbalance often occur simultaneously in saline ground water, and they might interact on the aquatic animals. The aim of this research is to evaluate the interaction of salinity and Na/K ratio in seawater on the growth of *L. vannamei* under laboratory conditions, thus to further the knowledge on shrimp farming with inland saline ground water.

MATERIALS AND METHODS

Source and Acclimation of Juvenile Litopenaeus vannamei

The experiment was carried out between June 14 and July 13, 2003. Juvenile *L. vannamei* were obtained from the Jiaozhou Shrimp Farm in Qingdao, China. When the shrimp were transported to the laboratory, one half was stored in two continuously aerated 600-l fiberglass tanks with natural seawater (29–31 ppt), and the other half was stored with diluted seawater (15 ppt) to undergo a 10-day acclimation to the indoor laboratory conditions, during which they were fed *ad libitum* twice a day (8:00 and

*Corresponding author. E-mail: dongsl@mail.ouc.edu.cn

18:00) with commercial shrimp ration pellets (composition: 41.58% crude protein, 8.36% crude lipid and 8.74% moisture; energy content: 19.37 kJ/g dry matter).

Experimental Design and Artificial Seawater Preparation

To eliminate the interference of imbalance from other ions, the experimental water was prepared by adding instant artificial sea-salts into fully aerated tap water. The instant artificial sea-salts were specially designed and produced by General Sea Salt Factory, Ocean University of China, in which the sodium and potassium ingredients were precisely compounded so as to keep their total concentration constant, whereas the Na/K ratios varied. The salinity of the newly prepared artificial seawaters was 30 ppt and 15 ppt and pH 8.2. At each salinity level, the total concentration of monovalent cations and other ions were kept approximately constant. Based on the former experiment result (Zhu et al. 2004), 5 Na/K ratios were set: 25.6, 34.1, 47.3, 102.1 and 153.3 (mmol/mmol), in which 47.3 was identical with the Na/K ratio of oceanic seawater, and it was set as control. The concentrations of Na⁺ and K⁺ were determined with an inductively coupled plasma-atomic emission spectrophotometer (ICP-OES; VISTA-MPX, VARIAN). The details are given in Table 1.

After the 10-day acclimation and 24 h starvation, shrimp of similar size were selected and weighted individually. To remove excess moisture, shrimp were blotted dry with paper towel and weighted to the nearest 0.001 g using an electronic balance. Two-hundred shrimp that weighted 1.554 ± 0.004 g (mean \pm SE) were selected, and 160 were randomly assigned to 40 glass aquaria (45 \times 25 \times 30 cm, 4 individuals/aquarium) to take the 30-day feeding trial. The aquaria were filled with 30 L artificial seawater of different salinities (15 ppt and 30 ppt) and Na/K ratios (25.6, 34.1, 47.3, 102.1 and 153.3). Therefore, 10 treatments, 4 replicates per treatment were conducted. The aquaria were randomly located. To prevent the shrimp from jumping out, every aquarium was covered with a mesh cover. The ambient temperature was controlled with an air-conditioner. Aeration was provided continuously and two-thirds of the water volume was exchanged every second day to ensure high water quality. During the experiment, dissolved oxygen was maintained above 6.0 mg/L, pH 8.1 ± 0.2 , water temperature at $25^\circ\text{C} \pm 0.5^\circ\text{C}$, and a simulated natural photoperiod (14 light: 10 dark) was used. The remaining 40 shrimp were dried in an oven at 65°C to constant weight, homogenized and stored at -20°C to estimate the body composition and energy content of the initial shrimp. During the feeding trial, the shrimp were fed fresh polychaete worms, *Neanthes japonica* (Izuka), which had been considered to be the best natural diet in prompting shrimp growth and was widely used in shrimp farming in China (Bi et al. 1995, Zhou & Xie 1995). The shrimp were fed at satiation level twice a day (6:00 and 16:00).

Samples Collection and Analysis

During the course of the experiment, the daily food (polychaete worms) supplied was blotted dry with paper towel and precisely weighed and recorded. The uneaten food and feces were collected by siphon within 3 h after each meal. Exuviae (molted exoskeletons) were collected and recorded at all times. The collected uneaten food, feces and exuviae were dried at 65°C and kept for further analysis. At the end of the experiment, all the test shrimp were starved for 24 h and then collected and dried at 65°C to constant weight. The shrimp from the same aquarium were pooled as a sample.

Nitrogen content was measured using Kjeltac Auto System 2200 (Foss, Sweden), and crude protein content was calculated from nitrogen content by multiplying 6.25 (AOAC 1984). Crude lipid was determined by the Soxhlet method (AOAC 1984). The energy content of dried samples was determined by Parr 1281 Oxygen Bomb Calorimeter (PARR Instrument Company, USA). Analyses of each sample were conducted in triplicates. The body composition of polychaete worm was analyzed in the same way as the shrimp samples and found to be: 83.6% moisture, 77.8% (dry matter) crude protein and 7.2% (dry matter) crude lipid; energy content was 21.31 kJ/g dry matter.

Calculation and Data Analysis

Weight gain (WG), specific growth rate (SGR), molting frequency (MF), feeding rate (FR), food conversion efficiency (FCE) and protein efficiency ratio (PER) were calculated as follows:

$$\text{WG (\%)} = 100(W_2 - W_1)/W_1$$

$$\text{SGR (\%}\cdot\text{day}^{-1}) = 100(\ln W_2 - \ln W_1)/T$$

$$\text{MF (\%}\cdot\text{day}^{-1}) = 100N_m / (N_s \times T)$$

$$\text{FR (\% body weight}\cdot\text{day}^{-1}) = 100C / [T (W_2 + W_1)/2]$$

$$\text{FCE (\%)} = 100(W_2 - W_1)/C$$

$$\text{PER} = (W_2 - W_1)/(C \times \text{Protein content})$$

Apparent energy or protein retention levels (ER and PR, respectively) were calculated as: $[(W_2 \times (\text{final energy or protein content}/100)) - (W_1 \times (\text{initial energy or protein content}/100))]/C \times (\% \text{ energy or protein in food}/100)$ (Hardy 1989).

Where W_2 and W_1 are the final and initial wet body weight of the shrimp, N_m is the number of molts, N_s is the number of shrimp, T is the duration of the experiment, and C is the total food consumed.

Statistics were performed with SPSS 10.0 statistical software (SPSS Inc., 1999). The assumption of homogeneity of variances was tested for all data, which were \sin^{-1} -transformed if necessary. Two-way analysis of variance (ANOVA) was used to test for the

interaction of salinity and Na/K ratio in seawater on all data. Significant ANOVAs were followed by a Student-Neumann-Keuls multiple comparison test to locate differences between groups. Significance was accepted when $P < 0.05$.

RESULTS

Survival and Molting

The survival and molting data of the test shrimp are presented in Table 2. During the 30-day experiment, there were 2 shrimp that died within one aquarium at salinity 30 ppt and Na/K ratio 25.6, and another 2 shrimp died while exposed to Na/K ratio 25.6 and 102.1 at salinity 15 ppt. However, no significant differences in survival among treatments were found ($P > 0.05$).

No significant interaction effects in molting frequencies (MF) were found, whereas the Na/K ratio had an effect ($P < 0.05$). At salinity 30 ppt, MFs for shrimp exposed to Na/K ratio 102.1 and 153.3 are much higher than for those exposed to lower Na/K ratios, even significantly higher than for the control (Na/K = 47.3) ($P < 0.05$). No significant differences in MFs were found among treatments at salinity 15 ppt, but it could be seen that MF increases, whereas Na/K ratio becomes higher.

Growth

At the beginning of the feeding trial, the body weights of the test shrimp under each treatment were similar (Table 2). At the end of the experiment, the final body weight of the shrimp were significantly influenced by salinity, Na/K ratio and interaction effects ($P < 0.05$). At salinity 30 ppt, the mean final body weight for shrimp at Na/K ratio 153.3 was significantly lower than for those at the other four Na/K ratios ($P < 0.05$), yet no significant differences in final body weight were found between shrimp exposed to the latter four ratios ($P > 0.05$). Shrimp at salinity 15 ppt had significantly higher mean final body weight than at salinity 30 ppt

($P < 0.05$). Na/K ratio showed no effects on shrimp final body weight at 15 ppt ($P > 0.05$), although it did at 30 ppt ($P < 0.05$). The mean final body weight for shrimp exposed to Na/K ratio 34.1 and 47.3 was higher than for those exposed to the other three ratios at both salinities.

Weight gain (WG) and specific growth rate (SGR) both were significantly affected by salinity, Na/K ratio and interaction effects ($P < 0.05$). At salinity 30 ppt, WGs of the shrimp exposed to Na/K ratio 34.1 and 47.3 were significantly higher than those exposed to Na/K ratio 25.6 and 102.1 ($P < 0.05$), and WG of the shrimp at Na/K ratio 153.3 was even lower ($P < 0.05$). However, no significant differences were in WG among Na/K ratios at salinity 15 ppt ($P > 0.05$), and the mean WG for shrimp at salinity 15 ppt was significantly higher than for that at salinity 30 ppt ($P > 0.05$). SGR has the similar tendency as WG.

Food Intake, Nutrient Retention and Food Conversion Efficiency

Data of food intake, nutrient retention and food conversion efficiency are presented in Table 3. No significant interaction effects were observed in feeding rates (FR) ($P > 0.05$), though salinity and Na/K ratio both showed an effect ($P < 0.05$). Shrimp at salinity 15 ppt had higher FRs than at salinity 30 ppt ($P < 0.05$). Although no significant difference in FR was found among Na/K ratios at salinity 15 ppt ($P > 0.05$), FR for shrimp exposed to Na/K ratio 25.6 showed the highest FR at salinity 30 ppt, which was significantly higher than for those exposed to Na/K ratio 34.1, 47.3 and 153.3 ($P < 0.05$).

Protein retention (PR) and energy retention (ER) were significantly affected by Na/K ratio and interaction effects ($P < 0.05$), whereas salinity showed no significant influence ($P > 0.05$). At salinity 30 ppt, PR of the shrimp at Na/K ratio 153.3 was significantly lower than of those at the other 4 Na/K ratios ($P < 0.05$), and no significant differences in PR were found between the latter 4 treatments ($P > 0.05$). At salinity 15 ppt, significant differences in

PR were only found between shrimp exposed to Na/K ratio 25.6 and 47.3 ($P < 0.05$). ER had the similar tendency as PR (Table 3).

Salinity showed no significant effects on food conversion efficiency (FCE) and protein utilization (PER) ($P > 0.05$). However, at salinity 30 ppt, FCE was significantly affected by Na/K ratios. The FCEs for shrimp exposed to Na/K ratio 34.1 and 47.3 were significantly higher than for those exposed to Na/K ratio 25.6 and 102.1 ($P < 0.05$), and the FCE for shrimp at Na/K ratio 153.3 was even lower ($P < 0.05$). However, no significant differences in shrimp FCE were found among different Na/K ratios at salinity 15 ppt ($P > 0.05$). PER showed the similar tendency as FCE.

Figure 1. Specific growth rate of *L. vannamei* reared at different salinities and Na/K ratios for 30 days. Means ($n = 4$), with letters significantly different within the same line ($P < 0.05$). Bars represent standard errors of the means.

Interaction of Salinity and Na/K Ratio on Specific Growth Rate and Food Conversion Efficiency

As presented in Table 2 and Figure 1, significant effects of salinity, Na/K ratio and interaction were found in SGR ($P < 0.05$). At both salinities SGR changed, whereas the Na/K ratio in seawater increased. However, the SGRs at salinity 30 ppt changed sharply, whereas those at salinity 15 ppt changed gently. At salinity 30 ppt, the SGR was low at Na/K ratio 25.6, but it mounted up rapidly at Na/K ratio 34.1 ($P < 0.05$) and then declined a little at Na/K ratio 47.3 ($P > 0.05$). Afterwards it made an acute drop at Na/K ratio 102.1 and 153.3 ($P < 0.05$), respectively. Although no significant differences in SGR were found at salinity 15 ppt, it still could be observed that SGR rose gently, whereas Na/K ratio increased from 25.6–47.3 and then declined when Na/K ratio continued to increase. At salinity 30 ppt, the maximum value of SGR occurred at Na/K ratio 34.1, whereas at salinity 15 ppt, the maximum value emerged when Na/K ratio was 47.3, though the two values were almost equal.

Interaction effects on FCE are pictured in Figure 2. Similar to SGR, changes of FCE at salinity 30 ppt were much more acute than those at salinity 15 ppt. At salinity 30 ppt, shrimp got the highest FCE when Na/K ratio was 34.1, and at salinity 15 ppt they got it, whereas Na/K ratio was 47.3. However, under Na/K ratio 34.1 and 47.3, the FCEs at salinity 30 ppt were much higher than those at salinity 15 ppt. Otherwise, the FCEs at salinity 30 ppt were lower than those at salinity 15 ppt under the other Na/K ratios (25.6, 102.1 and 153.3). As a result, no significant differences were found between the mean values of FCEs at the two test salinities ($P > 0.05$).

DISCUSSION

It is known that *L. vannamei* can tolerate a wide salinity range from brackish water of 1–2 ppt to hypersaline water of 50 ppt (Stern et al. 1990, McGraw et al. 2002). Boyd (1989) considered

Figure 2. Food conversion efficiency of *L. vannamei* reared at different salinities and Na/K ratios for 30 days. Means ($n = 4$), with letters significantly different within the same line ($P < 0.05$). Bars represent standard errors of the means.

salinity of 15–25 ppt to be ideal for *L. vannamei* culture. But, in view of inconsistencies in published information regarding salinity effects on shrimp survival and growth, the optimum salinity for *L. vannamei* is still not conclusive. Bray et al. (1994) showed that 5 and 15 ppt treatments produced significantly greater final weights than other levels (25, 35 and 49 ppt) tested. However, Ponce-Palafox et al. (1997) concluded that the growth of *L. vannamei* was not reduced at the salinity range of 25–45 ppt, and there were significant interaction effects of salinity and temperature on the growth and survival rates of the shrimp. Laramore et al. (2001) found that the effects of salinity on growth varied with size/age. In this research, it is clear that interaction of salinity and Na/K ratio in seawater has significant influence on the growth of *L. vannamei* (Table 2). The mean final body weights, weight gains and specific growth rates of the shrimp at salinity 15 ppt were significantly higher than those at salinity 30 ppt ($P < 0.05$), but it should be noted that good growth had always been obtained under Na/K ratio 34.1 and 47.3 at both salinities. At salinity 15 ppt, no significant effects were found in growth between treatments of different Na/K ratios ($P > 0.05$), whereas the growth of shrimp under Na/K ratio 34.1 and 47.3 were much better than under the other ratios at salinity 30 ppt ($P < 0.05$).

Customarily, salinity is one of the most compelling factors to most marine animals, but the ionic composition of saline water seems to be more important than salinity with regards to its effect on shrimp survival and growth (Davis et al. 2002, Saoud et al. 2003). Cawthorne et al. (1983) demonstrated that single salt solutions (NaCl) were not suitable for shrimp culture at any salinity. Additionally, Atwood et al. (2003) found that *L. vannamei* larvae could survive well in the solution containing 1 g/L sea salt, and they could survive fairly well after adding 4 g CaCl_2 or 2 g CaCl_2 and 2 g NaCl and the salinity reached 5 g/L, but no survival would have resulted if 4 g NaCl had been added. They speculated that sodium ratio to some other ion in the solution may be too high. Zhu et al. (2004) demonstrated that high Na/K ratio in seawater resulted poor survival of *L. vannamei*. In this experiment, the effects of salinity on growth, nutrient retention and food conver-

sion were much less than that of Na/K ratio and even interaction (Table 2, 3).

The importance of Na/K ratio might because of the indispensable role of potassium in crustacean osmolality maintenance and Na^+/K^+ ATPase activity (Winkler 1986, Vargas-Albores & Ochoa 1992). It has been demonstrated in some penaeids that the sodium and/or potassium hemolymph concentrations were modified according to the concentration of these ions in the external medium (Castille & Lawrence 1981, Dall & Smith 1981). Potassium is important in the activation of Na^+/K^+ ATPase (Mantel & Farmer 1983), which is involved in ion transport and osmoregulation. In the K^+ -free saline, oxygen consumption of the excised gills of the shore crab *Carcinus mediterraneus* was reduced by almost 40% (Lucu & Pavicic, 1995), it suggested that 30% to 40% of the energy liberated by gill respiration is used by the branchial Na^+/K^+ ATPase enzyme complex, maintaining Na^+ and K^+ concentration gradients between the extracellular and intracellular compartments. The central role of the Na^+/K^+ ATPase in the crustacean gill epithelium and the sodium gradient that is used to drive numerous processed has been described (see Lucu 1990). The variation of salinity (ionic intensity) may directly affect the ionic gradients between the extracellular and intracellular compartments of the shrimp, which would inevitably impact the activity of Na^+/K^+ ATPase, thus the interaction between salinity and Na/K ratio occurs.

Because of the limitation of labor and space, low salinity (≤ 5 ppt) was not included in this experiment, and only 2 salinity levels (30 and 15 ppt) were tested, which made a flaw to the research. However, the result at 15 ppt might give some inspiration on the comprehension of effects of Na/K ratio at low salinity. Na/K ratios within the experimental range (25.6–153.3, mmol/mmol) showed little impact on the growth of *L. vannamei* at 15 ppt, which indicated that the shrimp were more adaptable to abnormal Na/K ratios at low salinity than at higher salinities. Additionally, a few recent literature have concerned the ionic challenge on the survival and growth of *L. vannamei* at low salinities and freshwater. McGraw and Scarpa (2003) demonstrated that necessity of potassium in “freshwater” (1 ppt) at a minimum concentration of 1 ppm for the survival of *L. vannamei* postlarval. It could be figured out that the 48-h survival of the shrimp did not differ significantly, whereas the Na/K ratio changed between 10 and 490 (mmol/mmol). Such results fairly coincided with the actions of the shrimp at salinity 15 ppt in the present study.

In conclusion, the interaction of salinity and Na/K ratio in seawater had significant effects on growth, feeding, nutrient retention and food conversion ($P < 0.05$) of *L. vannamei*. The shrimp were more adaptable to abnormal Na/K ratios at low salinity than at higher salinities, and good growth could always be obtained within a Na/K range of 34.1–47.3 (mmol/mmol) regardless of salinity. However, further research was needed to confirm the proper range of Na/K ratio for the growth of shrimp at low salinities (≤ 5 ppt).

INFLUENCE OF FEEDING ON HEPATOPANCREAS STRUCTURE AND DIGESTIVE ENZYME ACTIVITIES IN *PENAEUS MONODON*

BOON LIONG ONG¹ AND DANIELLE JOHNSTON^{2*}

¹School of Aquaculture, University of Tasmania, Locked Bag 1-370, Launceston, Tasmania, 7250, Australia; ²WA Fisheries and Marine Research Laboratories, PO Box 20, North Beach, Western Australia 6020, Australia

ABSTRACT This study examines the influence of feeding on digestive enzyme activities in the black tiger prawn, *Penaeus monodon*, using histological and biochemical techniques. Juvenile *P. monodon* (>50 mm total length) were sacrificed after feeding at sequential time intervals, with unfed controls also sacrificed at the same time intervals. Resin histology revealed that there were no morphological changes in the digestive gland F-cells between fed and unfed *P. monodon* over time. There were no significant changes in α -amylase specific activities in fed animals over time post feeding, nor were there any changes in starved animals through time. Trypsin and α -glucosidase activities were significantly higher in unfed animals than fed animals. There was a significant peak in α -glucosidase activities at 0 min post feeding but this could not be conclusively determined as an influence from feeding because of high variability and the near negligible levels of α -glucosidase activities. A peak in lipase activity was observed at 60 min post feeding, but because there was no significant differences in lipase activities between fed and unfed animals it was therefore inconclusive. Results from histological and biochemical analyses failed to prove that feeding had a significant influence on digestive enzyme production of *P. monodon* and suggest that digestive enzyme production in *P. monodon* may be continuous and is not strongly influenced by feeding.

KEY WORDS: shrimp, digestive enzymes, F-cells, feeding, hepatopancreas, lumen, *Penaeus monodon*

INTRODUCTION

The most widely cultured prawn within the commercial prawn farming industry is the black tiger prawn, *Penaeus monodon*, because it has rapid growth rates and is larger than other farmed prawns at harvest. On such farms, food is often the highest operational cost (Chanratchakool et al. 1998). To be cost effective, prawn farms must achieve and maintain high feeding efficiencies while lowering food wastage. These requirements have paved the way for research into feeding strategies and penaeid enzyme studies, amidst other husbandry and nutrition studies.

Knowledge of penaeid enzyme dynamics, which is biologically important for the culture of these animals, has only been provided by generalist observations between feeding and/or feeding behavior in relation to digestive and cellular processes, or by direct histological examination. A continuous digestive enzymatic activity allows maximal digestive efficiency at all times but incurs a higher energy cost. Conversely, an induced response of increased enzyme secretion after food ingestion allows the organism to put more energy into somatic and/or gonadal growth because energy is not largely spent on continuous enzyme production. By clarifying the physiological aspects of feeding on the digestive functions, improved management of the cultured animals may be achieved.

Digestion in penaeids is facilitated by the hepatopancreas, which has several key roles including secretion of digestive enzymes, digestion and absorption of nutrients, storage of reserves and disposal of waste products (Al-Mohanna et al. 1985a, Al-Mohanna et al. 1985b, Al-Mohanna & Nott 1987, Vogt 1993). It is bilobed and comprises numerous blind-ending tubules (Gibson & Barker 1979, Dall 1992, Brunet et al. 1994, Vogt 1994). These tubules are lined by epithelial cells, which are differentiated into 4 distinct types: E- (embryonic), F- (fibrillar), B- (blister-like) and R- (resorptive) cells (Jacobs, 1928). F-cells are involved in enzyme secretion. Al-Mohanna et al. (1985a), observed vesicles budding from Golgi bodies in the F-cells of fed green tiger prawn *Penaeus*

semisulcatus and suggested that these vesicles were enzyme precursors or zymogens, but this is yet to be confirmed or observed in other penaeids (Dall 1992, Icely & Nott 1992). Vesicles were also observed in F-cells of the crayfish *Astacus astacus* after artificial draining of gastric juice (Vogt et al. 1989, Vogt 1996). The presence of digestive enzymes within these vesicles has been demonstrated by several authors with the use of immunohistochemistry (Malcoste et al. 1983), immunofluorescence (Vogt et al. 1989) and in situ hybridization (Van Wormhoudt et al. 1995).

The direct influence of feeding on enzyme production has been demonstrated in the European lobster *Homarus gammarus* by Barker and Gibson (1977). Using histology, they observed the discharge of supranuclear contents (digestive enzymes) from secretory cells after ingestion. Barker and Gibson (1978) found a similar trend from an identical experiment on the mud crab *Scylla serrata*. Similar results were also observed by Al-Mohanna et al. (1985a) in *P. Semisulcatus*, with the appearance of numerous zymogen granules in the F-cells corresponding to a maximal rate of enzyme discharge into the tubule lumen.

This study aims to clarify the effects of feeding on digestive enzyme production on the commercially important prawn *P. monodon* using histological and biochemical methods. By applying both techniques, confirmation of the effects of feeding on the hepatopancreas will hopefully be possible. The specific aims of this study are to examine the dynamics of the digestive gland in response to a single feeding event, by documenting changes in the structure of the hepatopancreas and the morphology of the F-cells and the specific activity of digestive enzymes. This was facilitated using a time series post feeding analysis on *P. monodon* juveniles.

MATERIALS AND METHODS

Animals and Husbandry

P. monodon post larvae were sourced from Rocky Point Prawn Farm, Queensland, Australia. The animals were housed in three 800-L tanks on a recirculation system and were fed daily to satiation with *Artemia* and commercial prawn pellets (Grobest 14, Primo Aquaculture).

Experimental Design and Procedure

The animals used in the experiment ($TL > 5$ cm) were randomly caught from the stock population using dipnets. Molt stage was determined by examination of setogenesis via changes in the seta on the margin of the inner uropod, in accordance with Smith and Dall (1985). Intermolt animals were randomly stocked into individual 1L containers to ensure that animals had equal access to feed and to prevent feeding hierarchies and cannibalism among conspecifics (Heinen 1987). The containers were then randomly allocated in the three holding tanks and kept afloat with Styrofoam sheets. The animals were placed under constant light to ensure that any enzymatic response was a function of feeding and not influenced by diurnal cycles. They were starved for 48 h to allow the animals to acclimatize to the containers as well as to ensure that stomach contents were emptied and that there would not be any residual effect from prior feeding regimes that would influence the results.

Fed animals were allowed to feed on commercial prawn pellets (Grobest T4, Primo Aquaculture) for 20 min. This feeding event was timed from the moment the animals collected the pellets with their periopods. At the end of 20 min, uneaten food was removed with a siphon. Unfed animals were disturbed in a similar fashion and were used as a control. At each of the times outlined in Table 1, five fed and five unfed animals were removed from their containers and placed in an ice slurry for 10 min to induce a chill coma.

The prawns were weighed and the hepatopancreas removed. Half the hepatopancreas was snap frozen in liquid Nitrogen and stored at -80°C for later digestive enzyme analysis. The remaining tissue was used for histology.

Wax Histology

One quarter of each hepatopancreas was fixed in Bouin fixative and processed routinely for wax histology. Sections ($5\text{ }\mu\text{m}$) were cut using a Microm HM 340 microtome and stained with Hematoxylin and Eosin for structural examination or with Mercuric Bromophenol Blue to elucidate the location of proteins (Chapman 1975). Sections were examined at $\times 100$ magnification with an Olympus BH-2 light microscope. Images were scanned with a microscope-mounted Leica DC 300F digital camera and examined on an IBM computer using an image manager, Leica IM50. To determine if tubule lumen size changed in response to feeding over time, five tubules per slide were randomly selected using a numbered grid and a random number table. The area of the lumen and

the tubule were measured using the freehand function of the image manager program.

Resin Histology

Approximately 2 mm^3 of hepatopancreas tissue from each animal was fixed in 5% glutaraldehyde in 2% sucrose-phosphate buffer pH 7.4 for 2–3 h, washed with 2% sucrose-phosphate buffer, dehydrated with ethanol and embedded in JB4 resin. Sections ($2\text{ }\mu\text{m}$) were then cut and stained with polychrome stain. Changes in cellular structure in response to feeding and elapsed time after feeding/disturbance were described with emphasis on F-cell morphology because they are the enzyme secreting cells (Al-Mohanna et al. 1985a, Vogt et al. 1989, Vogt 1996).

Enzyme Extraction

Hepatopancreas tissue was thawed on ice and homogenized using an Ultra Turrax electric homogenizer (IKA-Werke, Germany) in 1 mL of chilled 0.1 M Tris 0.02M NaCl pH 7.0 buffer for 1 min. The homogenate was centrifuged at 10,000 rpm for 5 min to pellet debris and solids and the supernatant (subsequently referred as enzyme extract) stored at -20°C .

Enzyme Assays

One enzyme unit was defined as the amount of enzyme that catalyzed the release of 1 μmole of product per minute and was calculated using the appropriate molar extinction coefficient (ϵ) in the assay conditions or a standard curve. Specific activity was defined as enzyme activity per mg of protein ($\text{Units mg protein}^{-1}$). Protein concentration was determined by the method of Bradford (1976) using bovine serum albumin as the standard. Spectrophotometric enzyme assays (200 μL microassays) were performed in duplicate at 37°C in IWAKI flatbottom microplates and absorbances read in a Tecan Spectro Rainbow Thermo microplate reader. Appropriate controls were included with each analysis. Tests confirmed that enzyme activities were linear with incubation time.

Trypsin

Trypsin activity was measured using N- α -benzoylarginine-p-nitroanilide (BAPnA) (Sigma B-4875) as the substrate. Each 200- μL assay contained 180- μL 0.2 M Tris 0.2 M NaCl pH 7.5 buffer, 10 μL BAPnA dissolved in dimethylformamide (DMF) and 10 μL enzyme extract. Trypsin activity was determined by measuring the release of p-nitroanilide at $A_{405\text{nm}}$ and using the molar absorption coefficient for p-nitroanilide, $9,300\text{ m}^{-1}\text{ cm}^{-1}$ (Stone et al. 1991).

α -Amylase

α -Amylase activity was measured using Ethylidene-pNP-G7 (E- pNP-G7) as the substrate. Each 200 μL assay contained 195 μL of Infinity amylase reagent (Sigma 568–20) and 5 μL enzyme extract (thawed on ice) at 37°C . α -Amylase activity was determined by measuring the release of p-nitrophenol at $A_{405\text{nm}}$ and using the molar absorption coefficient for p-nitrophenol, $10,130\text{ m}^{-1}\text{ cm}^{-1}$.

α -Glucosidase

α -Glucosidase activity was measured using p-nitrophenol α -D-glucopyranoside (Sigma N-1377) as the substrate. Each assay, performed in a 37°C water bath, contained 350 μL 0.1 M Tris 0.02 M

TABLE 1.
Experimental times for feeding/disturbance and sacrifice.

Time	Time When Fed Animals Were Sampled	Time When Unfed Animals Were Sampled
0 min	Immediately after feeding event	Immediately after disturbance
30 min	30 min after feeding event	30 min after disturbance
60 min	1 h after feeding event	1 h after disturbance
120 min	2 h after feeding event	2 h after disturbance
240 min	4 h after feeding event	4 h after disturbance
480 min	8 h after feeding event	8 h after disturbance

NaCl pH 7 buffer, 100 μL 0.02 M p -nitrophenol α -D-glucopyranoside and 50 μL enzyme extract. Aliquots (20 μL) of the assay mixture were removed at 1 min and 40 min after addition of the enzyme extract and added to 180 μL 1 M Na_2CO_3 to stop the enzyme reaction. α -Glucosidase activity was determined by release of p -nitrophenol at $A_{400\text{nm}}$ and using the molar absorption coefficient for p -nitrophenol, $18\,300\text{ m}^{-1}\text{ cm}^{-1}$ (Erlanger et al. 1961).

Lipase

Lipase activity was measured using 4- p -nitrophenol caproate (4NPC) (SigmaN-0502) as the substrate. Each 200 μL assay contained 190 μL 0.5M Tris 0.1 M NaCl pH 8.5 buffer, 10 μL of 2.5 mM 4NPC in ethanol and 10- μL enzyme extract (thawed on ice) at 37°C. Lipase activity was determined by measuring by the release of p -nitrophenol at $A_{405\text{nm}}$ and using the molar absorption coefficient for p -nitrophenol, $19\,800\text{ m}^{-1}\text{ cm}^{-1}$ (Gjellesvik et al. 1992). A blank assay containing only 195 μL buffer and 5 μL substrate was also performed for each sample to deduct background absorbance from actual enzyme activity measurements.

Statistical Analysis

Chi-square tests of independence were used to determine if the area of tubule lumen changed as a function of feeding over time. The occurrence of autolysis in some animals resulted in insufficient replicates for statistical comparison ($n < 3$) of hepatopancreas structure from the sampling times of 120 min and 480 min post feeding. As a result, only the remaining 4 sampling times (0 min, 30 min, 60 min and 480 min post feeding) were analyzed from the histology. Orthogonal analyses of variance (ANOVA) were used to determine the effect of feeding on production of digestive enzymes. Homogeneity of variances was assessed using residual plots, and data were transformed with a square root transformation when the assumption of homogeneity of variances was violated.

RESULTS

Structure of the Hepatopancreas

The penaeid hepatopancreas consisted of numerous blind-ending tubules, each made up of a number of epithelial cell types. The epithelial cells rest on a basement membrane and surround a central lumen (Fig. 1A). F-cells stained positively in a darker blue with Mercuric Bromophenol Blue caused by the presence of proteins (Fig. 1B). The other cell types stained light blue except for the nucleus, where nuclear material was dark blue (Fig. 1B). Greater structural detail revealed from resin histology showed F-cells also had pink patches within the cytoplasm but their composition could not be determined from the polychrome stain (Fig. 1C).

There were no apparent differences in the morphology of the F-cells between the fed and unfed animals, nor were there any structural changes over time post feeding. There were also no zymogen granules or digestive vesicles observed.

The area of lumen did not change significantly over time post feeding ($F = 2.703$, $\text{df } 3, 23$, $P = 0.069$). It was also not significantly different between fed and unfed animals ($F = 2.448$, $\text{df } 1, 23$, $P = 0.131$). The mean lumen area was $37.8 \pm 6.7\%$ of the tubule area.

Digestive Enzymes

All of the enzymes tested were present in the hepatopancreas of the fed and unfed animals (Table 2), although activities were variable between individuals. The orthogonal ANOVA revealed that the interaction between enzyme dynamics, effect of feeding and

TABLE 2.

The mean specific activities ($\mu\text{mol min}^{-1} \text{mg protein}^{-1}$) of the enzymes from the hepatopancreas of fed and unfed *P. monodon* juveniles, with standard error and coefficient of variation.

	Trypsin	α -Amylase	α -Glucosidase	Lipase
Fed				
mean \pm SE	2.61 ± 0.64	18.41 ± 1.9	$0.6 \times 10^{-3} \pm 4.88 \times 10^{-8}$	0.39 ± 0.03
CV	1.27	0.54	3.9×10^{-4}	0.38
Unfed				
mean \pm SE	5.06 ± 1.84	25.48 ± 26.72	$1.4 \times 10^{-3} \pm 2.8 \times 10^{-8}$	0.37 ± 0.01
CV	1.92	5.55	1.04×10^{-3}	0.18

elapsed time post feeding was not significant (Table 3). Therefore fed and unfed animals were grouped together when examining enzyme dynamics over time, and vice versa.

Trypsin

Trypsin specific activity in the unfed animals was twice as high as that of fed animals (Table 2, 3). There were no significant differences in trypsin specific activity over time post feeding/disturbance (Table 3).

α -Amylase

There were no significant differences in α -amylase specific activity between fed and unfed animals (Table 2). In addition, α -amylase specific activity did not change significantly over time post feeding/disturbance (Table 3).

α -Glucosidase

Although α -glucosidase specific activities in both fed and unfed animals were low, the specific activity of α -glucosidase in the unfed animals was 3-fold higher than that of fed animals (Table 2). α -Glucosidase specific activity also significantly differed over time (Table 2). Specific activity at 0 min was approximately four times higher than the activity at 240 min post feeding/disturbance (Fig. 2).

Lipase

There was no difference in lipase specific activity between fed and unfed animals (Table 2). However, lipase activity differed significantly over time (Table 2). Lipase activity remained relatively constant at 0 min and 30 min then peaked at 60 min after which the activity declined significantly through to 480 min post feeding/disturbance. Lipase activity at 60 min post feeding was twice the activity than at 480 min post feeding/disturbance (Fig. 3).

DISCUSSION

This study is the first to examine the effect of feeding on digestive enzyme production in the commercially important black tiger prawn *P. monodon* using the combination of sensitive techniques, resin histology and spectrophotometric biochemical assays. These methods yield quantitatively more robust results than enzyme histochemical visualization used by Barker and Gibson (1977), histological analysis on F-cell differentiation after feeding via chemical tracers used by Al-Mohanna et al. (1985a) and immunohistochemistry with radiochemical tracers by Vogt et al. (1989). Most of previous research on digestive enzyme activities, as listed in Tables 4 and 5, were not used for analyzing the effect of feeding on digestive enzyme production, but were performed on animals that were fed constantly prior to analysis.

Furthermore, the short 20 min feeding period in this experiment was used to initiate a feeding response and associated digestive enzyme production and to allow for sampling at 30 min post feeding/disturbance (Table 1). A longer feeding period or the complete filling of the animals' gut was not necessary for the commencement of enzyme production. The 48-h starvation period for the animals was also implemented to ensure an empty gut prior to commencement of the experiment. This starvation period was sufficient and similar to the duration used by Al-Mohanna et al. (1985a) on *P. semisulcatus*. A week-long starvation period used on *A. astacus* by Vogt et al. (1989) was considered too long for a smaller tropical decapod like *P. monodon*.

The histological and biochemical results from this study suggest that *P. monodon* has a continuous digestive enzyme production, regardless of feeding, and contradicts previous studies that suggested an influence of feeding on enzyme production.

Effect of Feeding on F-cell Structure

The positive reaction of F-cells to Mercuric Bromophenol Blue confirms their role in digestive enzyme production. The negative reaction by B- and R-cells to Mercuric Bromophenol Blue also

TABLE 3.

Interactions between and among factors for the 4 examined enzymes.

Enzyme	Interaction (Time \times Treatment)	Time	Fed Versus Unfed
Trypsin	F = 0.592, df 5, 43, $P = 0.706$	F = 0.409, df 5, 43, $P = 0.84$	F = 11.741, df 1, 43, $P = 0.001$
α -Amylase	F = 0.799, df 5, 43, $P = 0.557$	F = 0.376, df 5, 43, $P = 0.863$	F = 3.884, df 1, 43, $P = 0.055$
α -Glucosidase	F = 0.417, df 5, 43, $P = 0.834$	F = 2.853, df 5, 43, $P = 0.026$	F = 9.998, df 1, 43, $P = 0.003$
Lipase	F = 0.462, df 5, 43, $P = 0.802$	F = 3.21, df 5, 43, $P = 0.015$	F = 0.08, df 1, 43, $P = 0.927$

Figure 2. Changes in activity of α -glucosidase in the hepatopancreas of *P. monodon* juveniles over time after a feeding event/disturbance. Means with different letters denote significant differences ($P < 0.05$).

confirms that these cells do not function in enzyme secretion. These findings are consistent with several other studies (Dall & Moriarty 1983, Al-Mohanna et al. 1985a). Resin histology revealed pink patches within the cytoplasm of F-cells in both fed and unfed animals, but the nature of the organelles could not be conclusively determined from the polychrome stain (Fig. 1C). However, it is likely that these pink patches were rough endoplasmic reticulum (rER) or Golgi bodies, based on comparisons with previous studies on F-cell structure (Dall & Moriarty 1983; Al-Mohanna et al. 1985a). These structures could be better identified with electron microscopy.

Examination of fed and unfed animals post feeding in this study revealed a lack of structural differences in F-cells of both fed and unfed animals post feeding/disturbance. There was no evidence to suggest that F-cells of *P. monodon* had a distinct response to feeding through either digestive enzyme production via formation of zymogen granules (Al-Mohanna et al. 1985a) or appearance of vesicles (Vogt et al. 1989). This differs from several studies where histology demonstrated the influence of feeding on enzyme production.

Barker and Gibson (1977, 1978) demonstrated a positive response of enzyme production post feeding in the F-cells of the European lobster *Homarus gammarus* and the mudcrab *Scylla Ser-rata* within an hour after feeding. They observed three bursts of digestive enzyme discharge over a period of 5 h post feeding from the F-cells in both species, with each burst of activity measured by visual assessment of the intensity of the colored reaction product

Figure 3. Changes in activity of lipase in the hepatopancreas of *P. monodon* juveniles over time after a feeding event/disturbance. Means with different letters denote significant differences ($P < 0.05$).

from histochemical sections. Al-Mohanna et al. (1985a) also reported a positive response of enzyme production post feeding in the F-cells of *P. semisulcatus* using electron microscopy, with one occurrence of enzyme production in the form of zymogen granules. However, it should be noted that no other authors have found zymogen granules in penaeids (Dall 1992, Icely & Nott 1992). Vogt et al. (1989) suggested that feeding had an influence on enzyme production, because enzyme vacuoles were observed in F-cells in fed crayfish *Astacus astacus*. The size of zymogen granules reported by Al-Mohanna et al. (1985a) were approximately that of Golgi bodies in F-cells and enzyme vesicles observed by Vogt et al. (1989) were similar in size to adjacent mitochondria. Although electron microscopy was not performed in the current study, F-cell organelles like Golgi bodies and mitochondria could be distinguished in resin sections. However, there was no evidence of zymogen granules or enzyme vesicles in the F-cells of *P. monodon*.

Furthermore, although these histological studies suggest that feeding influenced enzyme secretion, there is ambiguity in their conclusions because no starved controls were used. Thus the authors did not definitively demonstrate the influence of feeding on enzyme production, therefore it is possible that disturbance caused by feeding may be contributing to the observed changes and needs to be confirmed with the use of starved controls.

Analysis of Lumen Area After Feeding

During digestion, digestive enzyme secretions flow from the F-cells of the digestive gland into the tubule lumen and ultimately into the primary duct and then the foregut. Chyme (digestive fluid from the foregut) also migrates from the foregut to the hepatopancreas via the same route. It has been suggested that as the prawns feed, the hepatopancreas tubules become loaded with chyme and fine particles masticated by the gastric mill (Al-Mohanna & Nott 1987). However, there have not been any studies to elucidate changes in the size of the tubule lumen as a response to feeding.

Based on suggestions that the hepatopancreas tubules would be filled with digestive enzymes and chyme during digestion, it was believed that the cross-sectional area of the lumen, as a percentage of tubule area, would expand and contract in response to the movement of fluids. However, this study shows that there was no significant change in lumen area, which suggests that the fluid flow (enzyme secretions or chyme) within the lumen of the tubules was either constant, or the rate of flow was not strong enough to cause a significant change in lumen area. A constant fluid flow within the tubule lumen is indicative that enzyme production was likely to be continual.

Digestive Enzymes of Fed Versus Unfed Animals Over Time

It has been reported that feeding triggers enzyme production in decapods (Barker & Gibson 1977, Barker & Gibson 1978, Al-Mohanna et al. 1985a, Vogt et al. 1989), as shown by higher enzyme activities in the fed animals over time. However, these authors did not conclusively demonstrate the influence of feeding on enzyme production, because starved controls were not used, so it is possible the enzymatic response may be because of disturbance at feeding rather than the feeding event itself. In this study, we did not find any evidence from the enzyme analyses to conclude that *P. monodon* also displayed a positive digestive response to feeding.

We found that there was no significant differences in amylase

activity between fed and unfed animals, or alternatively that trypsin and α -glucosidase activities in the fed animals were significantly lower than those in the unfed animals. The increased trypsin and α -glucosidase activity in unfed animals could be because of starvation. Prawns have been shown to use carbohydrate, lipid and protein reserves sequentially during starvation (Cuzon et al. 1980), which may be depleted after approximately 2 days of starvation (Stuck et al. 1996). Therefore, it is possible that the extended starvation period imposed on the unfed animals during the experiment's preparation in this study could thus have caused the increase in trypsin and α -glucosidase activity.

Hernandez-Cortes et al. (1999) also found no significant difference in trypsin activity between fed and unfed *P. vannamei*. This lack of significant difference in trypsin activity as demonstrated by Hernandez-Cortes et al. (1999), supports our findings that feeding did not have an influence on enzyme production, which would be indicated by an increase of trypsin in fed animals.

In this first examination of lipase activities in *P. monodon*, it was found that lipase activity peaked at 60 min post feeding, which was twice the activity at 480 min post feeding (Fig. 3). There was also a decreasing trend of enzyme activities over time observed in the α -glucosidase assay (Fig. 2). Both these trends are common for fed and unfed animals, because of the lack of significance in the orthogonal ANOVA, and they suggest that this trend may be caused by disturbance and not actual provision of feed.

Comparison of Examined *P. monodon* Enzyme Activities With Other Decapods

The trypsin activities in *P. monodon* were similar to reported activities in most penaeids (Table 4). The higher trypsin activity in *C. maenius* is probably caused by its mainly carnivorous diet. Trypsin activity is influenced by the amount of protein and protein source in the diet. This was demonstrated by Lee et al. (1984), who found that *P. vannamei* fed a diet with a 38% protein inclusion gave a significantly higher protease activity. Smith et al. (1985), found similar results with *P. vannamei* when the diet used had a 36% protein inclusion. Because the amount of protein in the commercial prawn pellets used in this study (39%) was similar to the protein inclusions in the diets used by Smith et al. (1985) and Lee et al. (1984), it could be assumed that the trypsin activity generated by *P. monodon* in this study was efficiently assimilating the protein in the diet.

Smith et al. (1985) also found that the protein source was more substantial than protein amount on influencing growth in medium and large animals (mean weights 9.8 g and 20.8 g respectively). Rodriguez et al. (1994) made a similar suggestion that trypsin activity could be influenced by diet. In their study, *P. japonicus* feeding on the algae *Chaetoceros gracilis* had six times more trypsin than animals feeding on *Artemia nauplii* (Rodriguez et al. 1994). Thus, the type of proteins in the diet must also influence the

trypsin activity. Because trypsin activity has been found in *P. monodon* in this study, it could also be safely assumed that other proteases like carboxypeptidases were present in *P. monodon* to complete protein digestion. These other enzymes, although not examined, were found to be present in other penaeids (Lee et al. 1984).

The α -amylase activity in *P. monodon* differed from the reported α -amylase activities in other penaeids (Table 4) and could be explained by different experimental treatments as well as genetic differences between species.

α -Glucosidase is necessary for the final liberation of glucose residues from oligosaccharides that have been formed from the hydrolysis of large carbohydrates by α -amylase. The low activity of α -glucosidase from *P. monodon* studied here was lower than reported activities (Table 5), but was likely to be sufficient for complete carbohydrate hydrolysis. It seems that penaeids have naturally low α -glucosidase activities, because nearly negligible α -glucosidase activities were also found in *P. indicus* and *P. vannamei* (Omondi & Stark 1995, Le Chevalier & Van Wormhoudt 1998).

Past research has also shown a crustaceans' ability to digest carbohydrates varies with the type of carbohydrates provided in the diet (Van Wormhoudt & Favrel 1988). Generally better growth has been attained in crustaceans with the use of complex carbohydrates than with simple mono or disaccharides (Van Wormhoudt & Favrel 1988). Because there is a wide range of carbohydrates found in naturally occurring food (Kristensen 1972), it seems appropriate that prawns would exhibit a diverse carbohydrase profile to exploit the range of dietary carbohydrates (Wigglesworth & Griffith 1994). The carbohydrases examined in this study are just two of the many carbohydrases described by other authors (Wigglesworth & Griffith 1994).

Deering et al. (1996) examined lipase activity in *P. monodon* but were not able to quantify the lipase activity, as it was only demonstrated with the use of a triolein/agar emulsion screening

(Table 5). Lipase activity was also found in other penaeids as reviewed by Jones et al. (1997) but was expressed as percent occurrence. There is currently a limited amount of literature on lipase activity in penaeids. As indicated by Le Vay et al. (2001), there should be more studies on lipid hydrolysis because current focus has been on penaeid proteases.

CONCLUSION

This study is the first to investigate the effect of feeding on the digestive enzyme production of decapods by using histological and quantitative enzymatic techniques. There were no trends that suggest feeding had an effect on the structure of the hepatopancreas or enzymatic activity. The morphological changes in the F-cells of other crustaceans examined by Barker and Gibson (1977, 1978), Al-Mohanna et al. (1985a) and Vogt et al. (1989) were not observed in this study. The lack of structural changes in the F-cells was further supported by the lack of conclusive results from the enzyme analyses. The commercial prawn feed used in this experiment contained all the necessary nutrients required by the prawns. Therefore it is expected that all the enzymes tested would be produced for proper digestion of the feed. Perhaps subsequent studies using monoingredient diets would be able to ascertain individual enzyme dynamics. In summary, the results from this study suggest a continuous enzyme production in *P. monodon*, which occurred even in the absence of food. These findings could be further confirmed by additional research with the use of continuously fed control animals.

ACKNOWLEDGMENTS

The authors thank Rocky Point Prawn Farm, Woongoolba, Queensland, Australia for supplying the prawns for this study and Dr. Natalie Moltschaniwskyj for her assistance in the statistical analyses.

ABSTRACT Using the percentage of mature females as an index, the reproductive period of the brown shrimp, *Farfantepenaeus californiensis*, off the coast of Sonora in Mexico, has been shown to occur throughout the year with two peaks of mass spawning. The objective of this study is to determine if a similar reproductive period occurred off Agiabampo, at the Sonora-Sinaloa border. By combining 3 indices of mature females: size structure, abundance and fecundity at size, a single egg production index (EPI) was calculated. Monthly samples from January through December 2002 were collected during 5 continuous days around the full moon (full moon \pm 2 days). Trawl net tows were used at depths from 1–9 m, 2 km north and south of the mouth of a coastal lagoon. Using the EPI, a single reproductive peak, May to August, was found, with May as the most important egg production month. On the other hand, the percentage of mature females showed a two peak reproductive period, one more intensive from May to August and the second one less intensive in November. We concluded that the best determination of the reproductive period of the brown shrimp required the use of three indices. Particularly off Agiabampo, this species has a well-defined reproductive period with just one massive spawning peak.

KEY WORDS: reproductive cycle, egg production index, shrimp, *Farfantepenaeus californiensis*, Gulf of California, Agiabampo

INTRODUCTION

Most studies about reproductive patterns in shrimp are based on the percentage of mature females (Mathews 1981, López-Martínez et al. 1999, López-Martínez et al. 2005, Leal-Gaxiola et al. 2001). This is a biased index of population reproduction and must be combined with an index of mature female abundance and fecundity-at-size data (García 1985). If one wants to find the most important period for population renewal, the studies of the reproductive biology of shrimp must take into account more than just reproductive percentage of mature females. Among others indices that have been considered for this target, we found a gonadal index, egg production for the population (Oh & Hartnoll 1999).

Reproductive studies of brown shrimp *Farfantepenaeus californiensis* (Holmes, 1900) are few (Olguín-Palacios 1968, Edwards 1978, Mathews 1981, Barreiro-Güemez 1986, Méndez-Tenorio 1986, Garduño-Argueta & Calderón-Pérez 1994, Leal-Gaxiola et al. 2001, Aragón Noriega & Alcántara Razo 2005). Using only the percentage of mature females, the reproductive period of brown shrimp was determined as continuous throughout the year with two peaks of massive spawning. In these reproductive studies, 2 main sources of data have been used: daily packing-plant sampling from commercial catches (September to May) off Sonora, (Leal-Gaxiola et al. 2001) and data from research cruises that evaluated shrimp populations off Sinaloa (Barreiro-Güemez 1986, Garduño-Argueta & Calderón-Pérez 1994). Sinaloa and Sonora comprise the eastern coast of the Gulf of California (Fig. 1).

The daily packing-plant data did not include all months of the year, but comprised a long data series (Leal-Gaxiola et al. 2001),

and for this reason many reproductive studies were based on these data. A disadvantage of this data is that abundance could not be evaluated but only percentage of mature females. On board sampling commercial trawl vessel are scarce, and temporally sporadic (Aragón Noriega & Alcántara Razo 2005). The advantage of on-board sampling is that an evaluation of abundance of mature female shrimp can be made.

Fecundity of brown shrimp has been described with a power equation with a value around 3 ($F = 0.0962 L^{2.9642}$, Mathews 1981). The quantity of eggs spawned by ripe females increased because of the increasing size of mature females (Mathews 1981).

Although the fecundity and reproductive pattern of brown shrimp off Sinaloa and Sonora have been determined, fecundity-at-size, abundance and size structure of mature females have not been combined in previous studies. The application of egg production index (EPI) in penaeid shrimp was proposed by Courtney & Masel (1997). They found that this index is a more quantitative measure of egg production in a population at a particular sampling station or sampling time. Aragón-Noriega (2005) used an EPI calculated from size structure, fecundity-at-size, and abundance of mature females to determine the maturity period of blue shrimp *Litopenaeus stylirostris* (Stimpson, 1874) in central Gulf of California.

Studies on reproduction of exploited species are critical not only for fisheries managers, but they also have a general scientific interest because spawning is the basis of population renewal and conservation of the stocks. With this in mind, we should look for more precise methods that can help to determine the maturity period of species with economical or ecological importance.

The objective of this study is to determine the reproductive period of brown shrimp off Agiabampo, at the Sonora-Sinaloa

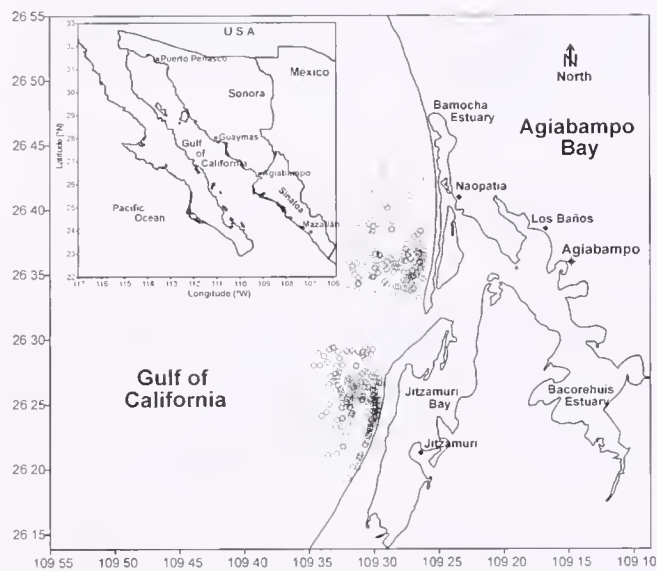

Figure 1. Study area and sampling zone.

state border, by combining the fecundity-at-size, abundance and size structure of mature females indices into a single index, EPI.

MATERIAL AND METHODS

Study Area

The Estero de Agiabampo (26.3°N, 109.3°W, Fig. 1) is a relatively long and narrow barrier lagoon created by sediment deposition of longshore currents. The broad region has a subtropical desert (BWh) climate (García 1988) and the sea surface temperature averages 30.4°C in July and 19.5°C in January.

Sampling

From January to December 2002, shrimp samples were taken each month for five continuous days (full moon ± 2 days). Collection was done with small boats, about 7 m long. We used trawl nets with a 15-m mouth and 32-mm mesh. Tows were made every 1.5 h at flood and ebb tides. This was done at depths from 1–9 m at locations ranging up to 2 km north and south of the mouth of the coastal lagoon (Fig. 1).

Sex, gonad maturity, total length (tip of the rostrum to tip of the telson) ± 1 mm and abdominal length of the samples was determined. Degree of gonad maturity was determined with the morphochromatic scale, comprising four stages (Leal-Gaxiola et al. 2001). For this study the specimens were grouped into immature (Stages I and II) and mature (Stages III and IV) categories.

Abundance of mature females was determined as specimens per hectare. This was done using a sweeping area described in Sparre & Venema (1995). Satellite geo-positioning devices locate the beginning and ending position of each trawl. The total of mature females was divided by the calculated area (in hectares). Fecundity-at-size was determined by the equations mentioned in Mathews (1981).

Egg production index (EPI), similar to one proposed by Aragón-Noriega (2005) was determined by combining size structure, fecundity-at-size and abundance of mature females. The EPI is formed as follows:

$$EPI = \sum_{i=1}^n F(PL_{ci}, a)$$

where: EPI is the egg production index, i is the i th size class, F is fecundity at size, L_{ci} is the mean value of length of class i , P is proportion of class i in a particular month, and a is the abundance of mature female in particular month.

RESULTS

A total of 5,780 specimens of all stages were collected (3,723 females and 2,057 males), yielding a female:male ratio of close to 2:1. However, for mature specimens, the ratio was 3:4, female:male ratio.

Period of Sexual Maturity

The percentage of mature males was more than 50% during the complete sampling period (Fig. 2). We found one period (May to August) in which the percentage of mature females was near or greater than 40% (Fig. 2). The other months in which mature females appeared were November (17%), April (10%) and February (1%).

Abundance

Monthly abundance of mature females determined by the sweeping area method were as follows: April, 29 females ha^{-1} ; May, 176 females ha^{-1} ; June, 97 females ha^{-1} ; July, 82 females ha^{-1} ; August, 58 females ha^{-1} and November, 5 females ha^{-1} (Fig. 3). These results show that spring and summer is the most important reproductive period for brown shrimp, using abundance and percentage of mature females.

Frequency of Sizes

Total length of mature males ranged from 90–160 mm, averaging 123 ± 1 mm and a 10% coefficient of variation. Total length of mature females for the entire study period was 110–190 mm, averaging 151 ± 1 mm with an 8% coefficient of variation. Male and female sizes were significantly different ($F_{(1,3100)} = 3255$, $P < 0.05$). Frequency of total length groups for May to August is

Figure 2. Monthly frequency of mature females (Stages III and IV) and males (Stage II) of the brown shrimp *Farfantepenaeus californiensis* off Agiabampo, Sonora-Sinaloa.

Figure 3. Abundance of mature brown shrimp females *Farfantepenaeus californiensis* off Agiabampo, Mexico.

shown in Figure 4. The modal size group was 44% greater than 165 mm in May. For June, July and August the percentage of specimens in the modal size group was 24%, 12% and 15%, respectively. Average total length of mature females was significantly greater in May ($F_{(3, 1428)} = 47.96, P < 0.05$). No significant differences were found in June, July and August (Fig. 5).

Eggs Production

The EPI in eggs•ha⁻¹ did not match with months of higher percentage of mature females. EPI indicates that May is the most

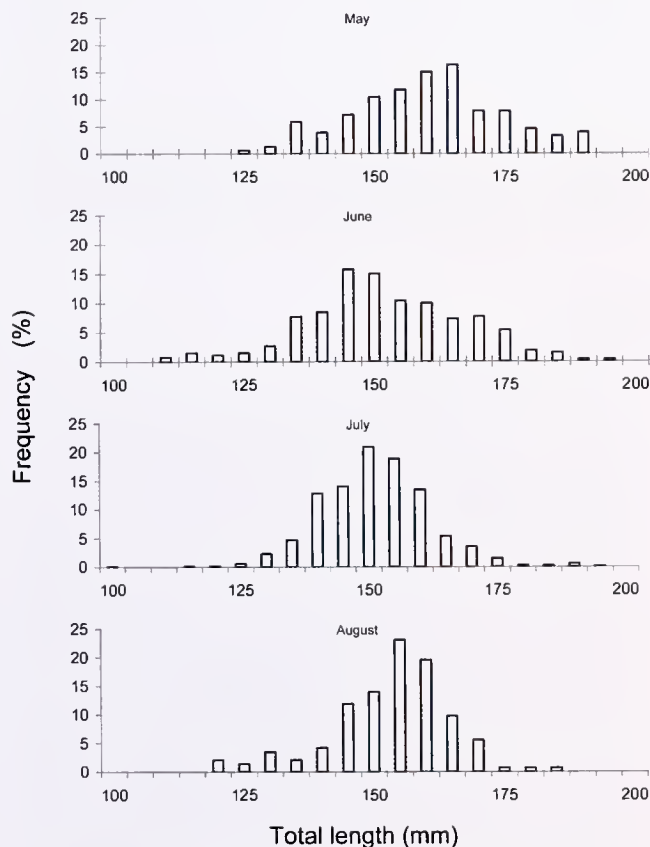

Figure 4. Size-structure of mature females (Stages III and IV) of brown shrimp *Farfantepenaeus californiensis* from May to August.

Figure 5. Comparison of average size between mature females (Stages III and IV) of brown shrimp *Farfantepenaeus californiensis* off Agiabampo, Sonora-Sinaloa

important month of potential egg production, followed by a clear negative tendency of EPI (Fig. 6). In May more than 60 million eggs•ha⁻¹ was the potential production on average. From June to August the average of potential eggs•ha⁻¹ were not more than 30 million. These results highlight the importance of using more than a single index to determine reproductive period for brown shrimp.

DISCUSSION

The reproductive period of brown shrimp *F. californiensis* off the coast of the Estero de Agiabampo is well defined as late spring to early summer, as quantified by using EPI. Leal-Gaxiola et al. (2001) found the reproductive period off southern Sonora as continuous during the year with two peaks of massive reproduction. However, those authors did not include data from June to September. For this reason their results are not adequate to determine the reproductive season for brown shrimp in that zone. The study of Leal-Gaxiola et al. (2001) could be easily combined with those of Méndez-Tenorio (1986) because this author sampled from June to January in the same zone and in the same years. Data from that study show an increasing percentage of mature females from June to August and decreasing percentage of mature females from August to January. The combination of data from the two studies

Figure 6. Eggs production per hectare of brown shrimp off Agiabampo, Sonora-Sinaloa.

yield a result similar to our findings. Leal-Gaxiola et al. (2001) found the times when the percentage of mature females was increasing and decreasing, but they erroneously concluded there were two periods of mass reproduction.

We found a single period of high rates of reproduction by using the percentage of mature females, similar to results found off Guaymas by Mathews (1981). He found mature females from February to November but a higher percentage from May to August. The reproduction period of brown shrimp reported off Mazatlán, Sinaloa is either continuous, with two periods of higher intensity (Garduño-Argueta & Calderón-Pérez 1994) or bimodal with a greater peak reproductive activity from March to May and a lower peak in October and November (Barreiro-Güemez 1986). García (1985) reviewed various types of spawning seasonal patterns of many shrimp species from around the world. He concluded that in spite of the shortcomings of the method (percentage of mature female) used for quantifying spawning activity, it seems that a bimodal pattern is most frequent. The main shortcoming of the percentage of mature female method is that overall population abundance of mature female is not taken into account but only a relative percentage of an unknown number per area (e.g., km⁻², ha or other measurement).

García (1985) also concluded that reproductive behavior of shrimp species respond to transition periods of temperature. In the Gulf of California well-defined periods of transition in temperature occurs from spring to summer and from fall to winter (Aragón-Noriega & Alcántara-Razo 2005). So, conclusion that brown shrimp display a double peaked spawning pattern where accepted mentioned that the reproductive period (determined by the percentage of mature brown shrimp females) in the Gulf of California depends on the SST.

Because the percentage of mature females is a biased index of population reproduction (García 1985), we combined 3 indices: abundance, fecundity and size structure of the mature female brown shrimp, representing the first published index for this species. The only other study of EPI application was conducted on *L. stylirostris* (Aragón-Noriega 2005). In May we found 44% of the mature females over 161 mm TL. From the fecundity-at-size pro-

posed by Barreiro-Güemez (1986), 44% of the females could be spawning 800,000 or more eggs. Though the higher percentage of mature females was collected in July, we propose that May is the most important month for the reproductive period of brown shrimp off Agiabampo, because the highest EPI was found this month.

The percentage of mature females in November suggests a second, less intensive spawning period, but EPI showed that only a 1-million eggs•ha⁻¹ was the potential production, on average, in that month.

To determine the actual maturity period of any species we should take into account all shortcomings of the available methods. A problem for an exploited species is the specimens that remain unaccounted for after the fishery season. For the case of the brown shrimp near Agiabampo we surmise that if the reproductive behavior of this species responds to transition periods of temperature (García 1985) the abundance of mature female remaining after the trawl fishery is too low to be considered as a two-peaked pattern species. The use of EPI could help to redefine the actual maturity period for those two groups of penaeid shrimp, even if the second period of spawning for browns has been greatly diminished by fisheries activities.

This study clearly shows that results from one area cannot be extrapolated to other areas of the Gulf of California. Also, we found that current commercial catch data are not adequate for determining the reproductive pattern of brown shrimp. We agree with the proposal of García (1985) to use at least two other indices, and not just the percentage of the mature females in samples. We conclude that the appropriate combination of indices include size structure of mature females, abundance of mature females and fecundity-at-size to determine the reproductive period of brown shrimp. Specifically, those three indices for the brown shrimp off Agiabampo show a single maturation period from May to August.

ABSTRACT Domoic acid (DA) the toxin responsible for amnesic shellfish poisoning (ASP) has proven problematic for king scallop *Pecten maximus* fisheries and aquaculture in Ireland. Toxin concentration in hepatopancreas of individual scallops and composite samples of gonad and adductor muscle of scallops suspended from a submerged longline, 2 m beneath the water surface and on a seabed site, 12–15 m beneath the suspended scallops were monitored from February 2003 to February 2004 at an aquaculture site in Clew Bay, Ireland. DA concentration in hepatopancreas of scallops from the seabed and longline peaked in April 2003, individual concentrations reaching 1037.1 $\mu\text{g}\cdot\text{g}^{-1}$ and 1212.6 $\mu\text{g}\cdot\text{g}^{-1}$ respectively. No statistically significant differences were exhibited between DA concentration in hepatopancreas of seabed and longline scallops except on 1 of the 10 sampling occasions. Slow depuration of DA toxin from hepatopancreas occurred from April 2003 to June 2003 and the concentration remained relatively stable from June 2003 to Feb 2004. Interpretation of DA concentrations in gonad were complicated by the lower concentrations recorded and the variable size of the gonad caused by the reproductive cycle over the 12-month study duration. DA concentrations in adductor muscle were below the limit of detection throughout the investigation. In summary DA concentration between scallops held in suspension or maintained on the seabed exhibited minor difference, and routine monitoring samples could be collected annually and held in suspended culture systems rather than using more expensive diver collection for sample procurement.

KEY WORDS: amnesic shellfish poisoning (ASP), domoic acid, *Pecten maximus*, scallop

INTRODUCTION

Amnesic shellfish poisoning (ASP) was first recorded in Canada in 1987 when over 100 people became ill after consuming mussels *Mytilus edulis* contaminated with the DA toxin. Early symptoms included nausea, gastroenteritis and vomiting followed within 48 h by neurological symptoms such as confusion, lethargy, disorientation and memory loss that persisted indefinitely; three of those affected in this outbreak died (Quilliam & Wright 1989, Todd 1993). The toxin, a small tricarboxylic amino acid belonging to the kainoid class of compounds, has been reported in 10 species of diatoms of the genus *Pseudo-nitzschia* (Bates 2000). Filter feeding bivalves such as scallops and mussels consuming these toxic phytoplankton species can accumulate the toxin to high concentrations (Zaman et al. 1997). Human consumption of shellfish contaminated with DA results in ASP.

Detection of DA in cultured mussels from Galicia, Spain in 1994 (Arévalo et al. 1997) and a range of Portuguese shellfish in 1995 (Vale & Sampayo 2001) led to the introduction of amendment 61/97 of EU Directive 91/492/EEC, which established the maximum allowable concentration of DA in whole shellfish or edible parts as 20 $\mu\text{g}\cdot\text{g}^{-1}$. Extensive shellfishery closures have since been recorded in many European countries, perhaps the most significant being those applied to the king scallop fishery off the west coast of Scotland from 1999 onwards, which resulted in considerable financial hardship for scallop fishermen (Gallacher et al. 2001, Smith et al. 2005). Prolonged closures of scallop fisheries in Europe because of elevated DA concentration persisting in some instances for months or years (Arévalo et al. 1998, Fernandez et al. 2000), slow rates of depuration in this species, localization of the majority of toxin in the hepatopancreas and high inter-animal variation between scallops led to the introduction of EU Commission Decision 2002/226/EC. This allowed harvesting of scallops with a whole body DA concentration exceeding 20 $\mu\text{g}\cdot\text{g}^{-1}$ if the parts to

be marketed, principally the adductor muscle and gonad, contained less than 4.6 $\mu\text{g}\cdot\text{g}^{-1}$. Scallop fishing from grounds that otherwise would have remained closed has been allowed, but this EU decision has necessitated that almost all the catch be processed in approved plants prior to sale. Restrictions on the sale of fresh scallops (in-shell), which have traditionally commanded a premium price compared with processed product, has resulted in a 2-tier market for fishermen, a high value one for fresh product, which can rarely be supplied and a lower value one for processed product.

In Ireland high DA concentrations in scallop recorded in late 1999 and early 2000 resulted in the closure of all scallop production/harvesting over the millennium period. Over the last 5 years, as in much of Europe, this toxin has proven particularly problematic in king scallop *Pecten maximus* fisheries. Recent DA concentrations of 618.2 $\mu\text{g}\cdot\text{g}^{-1}$ reported in April 2005 in mussels *Mytilus edulis* from the west coast of Ireland represented the first time the toxin had been detected above 50 $\mu\text{g}\cdot\text{g}^{-1}$ in this species. Interest in DA concentrations in scallop suspended in the water column compared with scallops on the seabed has been expressed from a number of perspectives. From an aquaculture perspective, scallops can be farmed either by sowing juveniles into seabed areas and harvesting at a later date or by more intensive culture in lantern nets suspended from submerged longlines. Both methods have been attempted in Ireland and in some bays both techniques have been used. Current legislation on the monitoring of DA refers to the number of shellfish to be used as a sample, the parts to be analyzed, the analytical technique to be used and the maximum concentrations. If differences in toxin concentration occurred between scallops produced by the two methods, then the possibility exists that scallops produced by one technique might be sold into a different market sector than the other, for example suspended scallops might have to be processed, whereas sown scallops from the seabed could be sold into the fresh market or *vice versa*. Given the higher value of fresh in-shell product, it is therefore conceivable that the production technique to be used in an area and the

*Corresponding author. E-mail: john.slater@lyit.ie

economics of scallop farming might be influenced by the likely toxin concentration in finished product. Such a possibility also raised the question that perhaps suspending scallops in shallower, phytoplankton-rich waters might increase rates of toxin depuration. Although bivalves that are actively feeding on nontoxic algae are likely to exhibit faster depuration (Bricelj & Shumway 1998), when mussels *Mytilus galloprovincialis*, contaminated with PSP toxin, okadaic acid, were transferred to a toxin-free zone the rate of depuration did not decrease significantly (Blanco et al. 1999). Nevertheless, the possibility that maintaining scallops in suspended culture nets until DA concentrations decreased to levels that allowed their sale into the more lucrative fresh market is worthy of further investigation for those faced with regular shellfish closures. The converse, whereby scallops suspended in waters containing a higher concentration of toxic species might accumulate more toxin than scallops on the seabed, should also be considered as a possible outcome of suspending scallops in the water column. Diver collection of farmed scallop has been proposed as a harvesting technique from intensive seabed plots. Though efficient as a means of scallop collection, such a technique is a slow method of harvesting, necessitating the holding of scallops for a period while a consignment is gathered. Concern has been expressed that during this holding period, scallops may accumulate toxins to levels such that their sale into the more valuable fresh market was no longer an option.

From a regulatory perspective, interest in DA concentrations in suspended versus seabed scallops centered on sample collection. In some inshore aquaculture sites in Ireland, divers are used for the collection of scallops for routine toxin monitoring. Recently introduced safety regulations for professional divers have resulted in an escalation of the costs associated with sample procurement using such methods. In circumstances where no differences existed between seabed and suspended scallops, sample provision for routine monitoring could be performed much more economically using scallops maintained for the purpose in suspended culture nets.

In addition to DA production from a range of *Pseudo-nitzschia* species, a benthic diatom, *Nitzschia navis virginea* has recently been reported as a further source of the toxin (Kotaki et al. 2004). The distribution of this species is at present largely unknown. If in a comparative study of DA concentration in seabed and suspended scallops, higher toxin concentrations were recorded in seabed scallops, DA production by benthic species might be suspected as a possible contributory factor.

Given the significance of results regarding DA toxin concentration in seabed and suspended scallops to fishermen, aquaculture producers, regulators and scientists; this comparative study was undertaken over a 12-month period at an aquaculture site on the west coast of Ireland.

MATERIALS AND METHODS

King scallop *Pecten maximus* were collected by diving from a seabed aquaculture site in Clew Bay, County Mayo off the west coast of Ireland and subdivided into 2 batches—a suspended batch, which was held in lantern nets 2 m below the water surface from a submerged longline and a seabed batch, which was returned to the seabed below the longline at a depth of approximately 12 m to 15 m (Fig. 1). Samples from both batches were provided for DA analysis at approximately monthly intervals from February 2003 to February 2004. Each sample comprised 12 individuals from each batch of mean shell length between 100 mm to 115 mm. On three

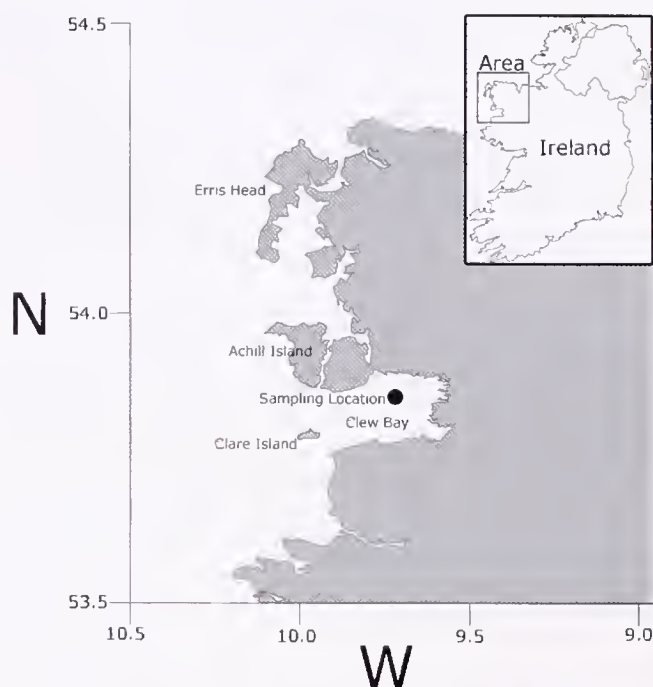

Figure 1. Sampling location in Clew Bay, County Mayo, Ireland.

occasions one or two shells in the longline sample were empty on arrival at the laboratory.

After shell measurement, scallops were dissected and the weight of total soft tissue and individual weight of hepatopancreas, gonad and adductor muscle recorded. The hepatopancreas of each scallop was analyzed individually to provide data on variability in DA concentration within each sample batch on each date. Composite samples of gonad and composite samples of adductor muscle from each sample group on each date were prepared for analysis, because previous studies suggested that DA concentration in these tissues would be much lower than in hepatopancreas; and hence differences, if present, between seabed and longline scallops would be more difficult to confirm because of the lower concentrations. Subsamples of composite tissues were analyzed in triplicate for DA toxin concentration.

DA was extracted from scallop tissue samples using procedures based on Quilliam et al. (1995) with several modifications. Extraction was performed from approximately 4.0 g of tissue homogenate with 16 mL of 50:50 extraction solvent (methanol:water) in a blender (Ultra Turrax T25, IKA-Works.) for 4 min at high speed. DA was extracted from each hepatopancreas individually. Where hepatopancreas weight exceeded 4.0 g, the organ was homogenized and a 4.0 g subsample used for extraction. After extraction, homogenates were centrifuged at 3,800 rpm for 30 min. A sample of supernatant was filtered using a methanol-compatible 0.45- μ m syringe filter and the combined concentration of DA and *epi*-DA in the filtered extract determined using a Shimadzu HPLC/UV and following equipment upgrade a Shimadzu HPLC/DAD (Mason Technology, Dublin). In those instances where the combined DA concentration exceeded that of the highest standard, the filtered extract was diluted with extraction solvent and the measurement of DA and *epi*-DA repeated. All solvents used were HPLC grade obtained from Lennox Laboratory Suppliers, Dublin. Mobile phase consisted of 10% acetonitrile and 1% TFA (trifluoroacetic acid) prepared with deionized water. HPLC flow rate was 0.5

mL.min⁻¹ and injection volume 20 µL. Calibration was performed externally using six DA calibration standards between 0.2 µg.mL⁻¹ to 10 µg.mL⁻¹ prepared from certified reference standard obtained from the NRC, Canada. Calibration curves were prepared for each sample batch and were always linear ($R^2 > 0.999$).

Statistical analysis of all data was performed using SPSS, Version 12.

RESULTS

Scallops used in this comparative study of DA toxin concentration were of a similar size (Table 1). Based on individual scallop measurements, the mean shell length and shell height for seabed scallops was 108.8 ± 3.9 mm by 96.4 ± 3.9 mm compared with 111.6 ± 5.2 mm by 99.4 ± 4.6 mm for longline scallops.

Mean DA concentration in the hepatopancreas of individual seabed scallops was 326.4 ± 169.9 µg.g⁻¹ compared with 313.9 ± 214.6 µg.g⁻¹ for longline scallops over the 12-month study at this location.

Mean DA concentrations in hepatopancreas and gonad of seabed and longline scallops on the 10 sampling occasions are provided in Table 1. DA toxin concentration in hepatopancreas of seabed and longline scallops exhibited similar trends over the 12-month duration (Fig. 2). The highest mean concentrations of DA in hepatopancreas were recorded on the second sampling occasion (April 3, 2003), individual DA concentrations reaching 1037.1 µg.g⁻¹ in seabed scallops and 1212.6 µg.g⁻¹ in longline scallops respectively. Comparison of the mean DA concentrations in hepatopancreas of seabed and longline scallops using a *t*-test demonstrated no statistically significant difference for 9 of the 10 samples. Only the sample from November 12, 2003 showed a significant difference ($n = 23$, $t = 3.263$, $\text{sig.} = 0.004$) in the mean DA concentration between seabed scallops (298.3 ± 89.4 µg.g⁻¹) and longline scallops (172.4 ± 95.7 µg.g⁻¹).

DA concentrations in composite samples of gonad tissue never exceeded the regulatory limit of 20 µg.g⁻¹ and were considerably lower than concentrations recorded in hepatopancreas. Overall mean DA concentrations based on triplicate analysis of composite gonad samples were 5.0 ± 2.1 µg.g⁻¹ in seabed scallops compared with 3.8 ± 1.9 µg.g⁻¹ in longline scallops. DA toxin concentration

in gonads of seabed and longline scallops exhibited considerable fluctuations and dissimilar trends over the 12-mo study duration (Fig. 2). Because DA toxin concentration of gonads is influenced by both the mass of DA in the intestinal loop within the gonad and the mass of gonad tissue itself, the reproductive condition of scallops from both sample batches was determined in an attempt to understand the fluctuations and trends over the 12-mo study (Fig. 3). Relative gonad height (RGH) in both sample groups showed a similar trend with peak RGH at the end of May. Seabed scallops exhibited higher RGH than longline scallops, although differences between sample groups were not significant ($n = 236$, $t = 1.448$, $\text{sig.} = 0.149$). The decline in RGH suggested a single prolonged spawning at this study location, although the use of monthly sampling for determination of the number of spawnings is not recommended (Slater 2005). Because of fluctuations in DA concentration within and between sample groups and varying reproductive condition over the 12-month study, the mass of DA in gonad was determined to examine if it better represented the changes in DA levels in gonad (Fig. 4). For comparative purposes the mass of DA in hepatopancreas was also determined (Fig. 4).

DA concentrations in composite samples of adductor muscle were below the limit of detection (LOD = 0.1 µg.g⁻¹) in all samples over the 12-month study duration.

DISCUSSION

DA concentrations in hepatopancreas were approximately 1 to 2 orders of magnitude greater than in gonad, hence if differences occurred between toxin concentration in longline and seabed scallops; such differences should be more easily recorded in those tissues having the higher DA concentration. Individual analysis of each hepatopancreas showed high inter-animal variability in DA concentration within each sample. Coefficients of variation (CV) of DA concentration in hepatopancreas of longline scallops ranged from 10.7% to 55.5% whereas that of seabed scallops ranged from 17.8% to 49.5%. The mean CV of DA concentration in hepatopancreas of longline and seabed scallops was 42.3% and 31.0% respectively. Similar high levels of inter-animal variability in DA concentration in king scallops have been reported (Campbell et al. 2001, Blanco et al. 2002, Bogan et al. 2006). Over the 12-month duration of the study similar DA concentrations in hepatopancreas

Values represent the mean ± standard deviation.

Figure 2. Concentration of DA in hepatopancreas (top) and gonad (bottom) of seabed and longline scallops from Feb 03 to Feb 04. (Each point represents Mean \pm St. Dev).

of longline and seabed scallops were reported and a statistical difference between the two sample batches occurred on only one occasion. Similarly no significant differences in PSP toxin concentration were reported in a comparative study between sea scallops suspended 2 m beneath the water surface and those on the seabed at 11 m depth (Haya et al. 2003).

Over the 12-month duration of the study both seabed and longline scallops demonstrated rapid accumulation of DA in hepatopancreas in March 2003, slow depuration during April 2003 to June 2003 followed by relative stability from June 2003 to February 2004. The fact that there was no statistical difference in DA content of hepatopancreas between longline and seabed scallops was somewhat unexpected. Reports of toxic *Pseudo-nitzschia* cells descending after a bloom from nutrient-poor surface waters into higher-nutrient mixed layers suggested that differential profiles in toxicity might have been anticipated between suspended and seabed scallops (Dortch et al. 1997, Trainer et al. 1998, 2000). A time

delay in PSP toxin accumulation in suspended and seabed scallops was suggested as toxic cells in surface waters descended towards the seabed as the toxic bloom subsided (Bricelj & Shumway 1998). In this study no temporal difference in peak DA concentration in hepatopancreas between longline and seabed scallops was recorded although this may have been caused by the long sampling intervals between February 26, 2003 to April 3, 2003 and April 3, 2003 to May 23, 2003.

Blooms of toxic *Pseudo-nitzschia* cells are often regarded as being widely dispersed throughout the water column, however they have also been reported as thin layers in the water column and following sinking as near-bottom thin layers, which may extend over large areas. Cell densities have been reported within these thin layers exceeding 10^6 toxic cells.l⁻¹ (Rines et al. 2002). The absence of a significant difference in DA concentration in hepatopancreas between longline scallops suspended 2 m beneath the water surface and seabed scallops from 12 m to 15 m depth, in all

Figure 3. Relative gonad height of seabed and longline scallops from Feb 03 to Feb 04. (Each point represents Mean \pm St. Dev.).

but one of the samples, suggested that the source of DA toxicity was relatively evenly distributed throughout the water column in this location.

After the depuration phase during April 2003 to June 2003, concentrations of DA in the hepatopancreas over the remaining 8 month (June 2003 to February 2004) were relatively stable with minor fluctuations between $170 \mu\text{g.g}^{-1}$ to $330 \mu\text{g.g}^{-1}$ suggesting that no further depuration of toxin from hepatopancreas occurred, rates of uptake and depuration of DA were balanced or that the rate of depuration was very slow and not recorded over the 8-month period. Prolonged toxicity over an extended period rather than a continual decline in toxicity may have arisen from the continued development of small pulses of toxic *Pseudo-nitzschia* cells. Such pulses can result from *Pseudo-nitzschia* cells that had sunk after nutrient depletion being brought back into surface waters during upwelling events (Trainer et al. 2000). This replenishment of cells into surface waters has been proposed as a mechanism to explain why some blooms appear to persist for up to 3 mo in the field and might also explain why toxicity persisted throughout this study (Bates et al. 1989, Smith et al. 1990). Extended periods of toxicity attributed to very slow rates of depuration have also been reported in sea scallops, *Placcopecten magellanicus* with PSP toxin over a 12-month period (Haya et al. 2003).

Many strains of domoic acid-producing diatoms have been reported, all belonging to the genus *Pseudo-nitzschia* except the benthic species *Amphora coffeaeformis* (Agardh) Kützinger (Bates 2000, Shimizu et al. 1989). Recently a benthic diatom, *Nitzschia navis-varingica*, collected from brackish water in Vietnamese shrimp ponds and identified as a new species has been demonstrated to be capable of DA production (Kotaki et al. 2000, 2004). Distribution of this benthic species is presently unknown although it has been reported in Japan and the Philippines and can be found in the water column (Lundholm & Moestrup 2000, Kotaki et al. 2004). The scallop toxicity results over a 12-month sampling period in this site provided no support for the hypothesis that DA production by benthic diatoms occurred.

DA concentrations in gonad were below the regulatory limit of $20 \mu\text{g.g}^{-1}$ throughout the study and never exceeded $10 \mu\text{g.g}^{-1}$ in

any composite sample of seabed or longline scallop gonad. Early results during the toxin accumulation phase in the hepatopancreas (March 2003) showed an expected increase in DA concentration in gonad. A corresponding decrease in DA concentration in gonad occurred from March 2003 to June 2003, although this was somewhat slower to commence in seabed scallops. During the period of relative stability in DA concentration in hepatopancreas (June 2003 to February 2004), DA concentrations in gonad fluctuated considerably and differences were exhibited between the two groups of scallops. To understand these fluctuations and between-group differences, the reproductive condition of the scallops using relative gonad height, a measure selected because it accounted for small differences in size between the scallop samples was examined. Because the DA is predominantly contained within the intestinal loop that passes through the gonad, it was expected that as the gonad increased in size DA concentration of gonad would decrease and *vice versa*. The results from the February 2003 to July 2003 period demonstrated the converse, as RGH increased and then declined after spawning, DA concentration in the gonad followed a similar trend. The results demonstrated that despite the variations in gonad size, DA concentration in the gonad was predominantly determined by DA concentration in the hepatopancreas, which exhibited a similar trend over the February 2003 to July 2003 period. The influence of gonad size on DA concentration in gonad was demonstrated by comparing toxin concentration between the scallop batches, higher RGH of seabed scallops being reflected in lower DA concentration whereas lower RGH of longline scallops was reflected in comparatively higher DA concentration. Fluctuations in DA concentration in gonad from Jul 03 to Feb 04 or variations between the two groups of scallop could not be explained by consideration of the RGH independently. In an attempt to explain the variations in DA concentration in gonad and gonad size, changes in the mass of DA in gonad were examined over the study duration. For comparative purposes changes in the mass of DA in hepatopancreas were also examined. Changes in the mass of DA in gonad over the 12-month period exhibited a similar trend to that for both the concentration and mass of DA in hepatopancreas. Because fluctuations in DA concentration of gonad from

Figure 4. Mass of DA in hepatopancreas (top) and gonad (bottom) of seabed and longline scallops from Feb 03 to Feb 04. (Each point represents Mean \pm St. Dev.).

July 2003 to February 2004 could not be attributed to changes in gonad size, it was concluded that fluctuations during this period, and variations between the two scallop batches must have resulted from high inter-animal variability in DA concentration in gonad and experimental error. DA concentrations in gonad have exhibited high inter-animal variability in several other studies (Arévalo et al. 1998, Campbell et al. 2001). Similar difficulties to those encountered in this study in interpreting changes in DA concentration in gonad have been reported elsewhere (FSA 2001). Although regulatory monitoring of DA concentration in gonad for determining its suitability for entering the food chain is vital, the low concentrations compared with other tissues, variations in go-

nad size during the reproductive cycle and difficulties encountered interpreting results, suggest that its value in understanding temporal changes is questionable.

ACKNOWLEDGMENTS

YMB was the recipient of Higher Education Authority Strand 1 postgraduate funding under the Technological Sector Research Programme supported by the Irish National Development Plan 2000–2006. The collection and provision of scallop samples was co-ordinated by Mr. Neil O'Boyle, Clew Bay Forum and funded by the Marine Institute.

SYMPOSIUM ON MOLLUSCAN FISHERIES AND AQUACULTURE

Papers presented at the:

World Congress of Malacology

Perth, Western Australia

July 11–16, 2004

SYMPOSIUM ON MOLLUSCAN FISHERIES AND AQUACULTURE

EDITED BY: GREG B. MAGUIRE,¹ FRED E. WELLS² AND LINDSAY M. JOLL²

¹*Research Division, Western Australian Department of Fisheries, Post Office Box 20, North Beach, Western Australia 6920, Australia;* ²*Western Australian Department of Fisheries, Locked Bag 39, Cloisters Square, Western Australia 6850, Australia*

The World Congress of Malacology was held on the campus of The University of Western Australia from July 11 to 16, 2004. The Congress, with a theme of *Molluscan Megadiversity: Sea Land and Freshwater*, attracted 300 mollusc workers from Australia and 41 overseas countries. Details of the congress can be found at: <http://www.molluskey.com/perth>

The Congress provided an opportunity to develop a symposium on molluscan fisheries and aquaculture that highlighted current progress in the field, particularly in the Australasian region. A total

of 35 papers were presented: 27 lectures and 8 posters. Fourteen of the papers presented at the symposium are printed in full in this issue. A list of the other papers presented at the congress, and their abstracts, can be obtained from the listed website.

The symposium on molluscan fisheries and aquaculture and publication of the papers was generously supported by the Australian Fisheries Research and Development Corporation, the Western Australian Department of Fisheries Development and Better Interests Fund and the Journal of Shellfish Research. We acknowledge with appreciation the contribution made by the referees of the various papers and the considerable help from Sharon Brown of the WA Department of Fisheries in formatting the papers.

Papers presented at the World Congress of Malacology Perth, Western Australia July 11 to 16, 2004

AN ASSESSMENT OF THE ENVIRONMENTAL IMPACT OF WILD HARVEST PEARL AQUACULTURE (*PINCTADA MAXIMA*) IN WESTERN AUSTRALIA

FRED E. WELLS^{1,2*} AND PETER JERNAKOFF³

¹Enzer Marine Environmental Consulting, PO Box 4176, Wembley, Western Australia 6014; ²Western Australian Department of Fisheries, Locked Bag 39, Cloisters Square, Western Australia 6850 (Present address); ³IRC Environment, 26 Colin Street West Perth, Western Australia 6005

ABSTRACT Typical operating procedures used in the wild harvest pearl aquaculture (*Pinctada maxima*) industry in Western Australia are described as a basis for examining the potential environmental impact of the industry. A risk analysis workshop was held, which included industry representatives, marine scientists, regulatory agencies and conservation interests. The goal of the workshop was to document the main potential environmental and ecological risks that arise from the various activities carried out by the *P. maxima* industry. Thirteen environmental and ecological issues were identified across the *P. maxima* fishery. None were considered to be high risks; all were ranked as either moderate (23%) or low (77%). Moderate risk rankings included: introduction of disease from seeding; attraction of other fauna and introduction of exotic organisms. Low risks were: spread of disease; introduction of disease from hatchery; introduction of disease from translocation; impact to protected and endangered species resulting from entanglement; impact of habitat; impact to protected and endangered species resulting from farm lighting; nutrient impacts in sediment; perceived change in water quality; potential for litter and reduction of primary productivity. The low ratings given to disease risks took into account current strict regulatory controls for minimizing disease risks. The industry is considered to be environmentally benign. However, recommendations are made on how to further minimize risk.

KEY WORDS: pearling, aquaculture, environment, *Pinctada maxima*

INTRODUCTION

The Western Australian pearling industry is a world leader, with a current average annual value of about \$125 million Australian. The Australian South Sea pearls produced are well regarded in the industry worldwide, and Western Australian companies have an enviable record for producing a high quality product. The pearling industry is unique in being a mix of wild capture and growout. It is the second largest successful aquaculture industry in Australia. In terms of dollar value, the fishery is second in Western Australia only to the western rock lobster, *Panulirus cygnus*. The industry is based on the pearl oyster *Pinctada maxima* (Jameson 1901), a bivalve mollusk species that has a widespread distribution in the Indo-Pacific and is not limited to Western Australia. Several other species of pearl oysters are cultured on a small scale in Western Australia, but are not covered in this article.

Pearl production has a long history in Western Australia, with the first recorded operations being in Shark Bay in 1850. In the early years, natural pearls were harvested from *Pinctada albina* (Lamarek 1819) collected intertidally or dredged from shallow water. Later shells became more valuable than the pearls and the industry was based on mother of pearl. No regulations were in place to sustainably manage the industry. As a result, pearl oysters were over collected, stocks became depleted and the fishery collapsed. The industry moved to the north coast of Western Australia where it centered on Broome and used the larger *P. maxima*. Shells were still the dominant product. By 1910 there were nearly 400 luggers and 3,500 people in the industry. However, when plastic buttons were introduced the industry crashed, and Western Australian pearling almost disappeared entirely during World War II. The industry made a comeback after the war with the beginning of the cultured pearl industry. The settlement of Kuri Bay started in 1956 and is still in operation (Shepherd 1975, Taylor 1985, Ander-

son 1996). In the early decades the fishery went through cycles of boom and bust, with the loss of men and boats through cyclones and other storms, loss of life and permanent injuries through diving mishaps and the bends, labor problems, racial tensions and fluctuating prices. Whereas there are still variations in the economic cycles, the industry is now highly organized and is geared to maintain sustainable production on an economically and environmentally sound basis. In this study we describe operations of the industry and assess its environmental impact.

INFORMATION SOURCES

This study combines information gathered in two studies. For the first study (Enzer Marine Environmental Consulting 1998), an extensive literature search was undertaken to obtain information on the industry and the possible environmental effects of it. Copies of regulatory requirements were obtained from appropriate agencies. Discussions about the perceived environmental effects of the industry were held with governmental officers and other people within and outside of the industry. An 8-day field trip to the North West was undertaken to obtain first hand knowledge of the industry and its practices. The trip included an examination of a pearl oyster hatchery in Broome, 3 days observing fishing operations off Eighty Mile Beach, including several dives on various bottom types during the collection of pearl oysters and on shell holding areas to examine for any effects of the bottom longlines. One day was spent in Roebuck Bay at Broome on a bottom culture farm to observe the effects of shell culture and structures close to the bottom in various bottom types in the area. Three days were spent in King Sound to examine how surface longline farms operate, the cleaning process, methods of handling various wastes and rubbish, etc. Two types of farms were visited, a shore-based farm and two that are sea based.

For the second study (Jernakoff 2002), a site visit was conducted to evaluate current pearl industry practices and procedures. The objectives of the site visit were to: visit three pearl farms (Bynoe Harbour, Northern Territory; Kuri Bay, Western Australia

*Corresponding author. E-mail: Fwells@fish.wa.gov.au

and Talbot Bay, Western Australia), fishing vessels and interview staff to assess how the fishery operates and how closely its procedures and practices are in line with those required of an internationally recognized environmental management system; assess the degree to which existing practices and procedures are implemented; and report on the site visit and evaluate physical conditions, existing practices and procedures of a pearl industry in operation in the Broome, Darwin and Kimberley region, the area of Western Australia that is northeast of Broome. During the visit the observed farming activities included growout, seeding and harvesting. The physical conditions were observed in which the activities operated and the extent to which management systems were implemented.

An environmental and ecological risk assessment workshop was then conducted in September 2001 based on existing knowledge, considering all aspects of the fishery, identifying and prioritizing gaps in knowledge and producing a set of prioritized risks. The workshop included eight representatives of industry, five fishery scientists and managers, four staff from regulatory agencies and two community environmental representatives. The goal of the workshop was to document and risk rank the main potential environmental and ecological risks that arise from the various activities carried out by the *P. maxima* industry. This risk register is used to identify the underlying issues so that these may be addressed through the development of an appropriate management strategy to reduce the risk of deleteriously affecting the ecosystem in which the industry occurs. The aim was also to integrate the workshop with a broader ecological sustainable development (ESD) research program by providing a session of the workshop for the Department of Fisheries Western Australia (DFWA) to address environmental and ecological risks for the wild harvest component of the *P. maxima* fishery. The identification of key environmental issues assisted in determining if adequate information on those issues exists or if information is required after a review of national and international literature.

At the environmental risk assessment workshop, participants were asked to list all of the sources of environmental problems that could potentially be caused by the industry. The potential sources were then entered into a risk matrix of likelihood and consequence. Each of these was assessed against a score varying from 1–6. A likelihood of 1 was considered to be remote, whereas 6 was considered to be very likely. If the event did occur, the consequence was judged against a scale where 1 was negligible and 6 was catastrophic. Multiplying the two scores together provided their position on the matrix. Scores of 20 and above were assessed as being of high concern, 7–19 were moderate, and 6 and below were low.

BIOLOGY OF *PINCTADA MAXIMA*

The pearl oyster, *P. maxima* is widespread in the Indo-West Pacific. In Western Australia it has been recorded as far south as Shark Bay, but it is not commercially fished south of North West Cape. The species is a protandrous hermaphrodite, maturing first as males at an age of 3 to 4 years and a size of 110–120 mm. As they age, the animals undergo a sex change and become female. By 170 mm half of the animals are males and half are females. By 190 mm the population is entirely female. Because the animals can spawn every year, each individual functions as both a male and then a female for several spawning seasons. Very few animals are simultaneous hermaphrodites. The breeding season is long, from

September to October to April to May; most spawning occurs from the middle of October to December, with a smaller secondary spawning in February and March (Rose et al. 1990, Rose & Baker 1994, Knuckey 1995).

Gametes are spawned into the water column and fertilization is external. Females release from 2–12 million ova each, with a diameter of 60 μm . Veliger shells form after 1 day, at an average size of 79 μm . The planktonic veliger stage is a distributional phase that allows the young pearl oysters to colonize new areas if suitable bottom can be found. The pediveliger stage is reached by day 22 to 24. The majority of veligers start metamorphosing into juveniles on day 24. Settlement occurs over days 28 to 35. In nature, when veligers are ready to metamorphose they settle to the bottom and search for a suitable habitat. If an appropriate area is found, they settle on it and metamorphose into the juvenile stage. If no suitable settlement site is located within a short period the animals metamorphose and die (Rose & Baker 1994).

After settling to the bottom, *P. maxima* is byssate and attached to the bottom during its juvenile and adult phases of the life cycle. It requires a hard surface for the initial attachment, and once it is attached to the bottom the connection is permanent. *P. maxima* lives on shallow rocky pavements on the continental shelf where there are small crevices into which the young animals can settle and develop. Like most bivalves, pearl oysters are filter feeders. Growth rates are initially fast. Field measurements at Eighty Mile Beach have shown that the animals reach the minimum legal size of 120 mm shell height in their third year of life. They are fished for 3 to 4 years before growing to a size of 160 mm, beyond which they are no longer suitable for round pearl culture. Large oysters of 200 mm are 15–20 y old (Joll 1996). The animals can reach a maximum of 270 mm (Rose & Baker 1994).

MANAGEMENT OF THE INDUSTRY

Pearling and pearl farms for *P. maxima*, are managed by the Department of Fisheries Western Australian (DFWA) under the provisions of the Pearling Act 1990. The definition of *P. maxima* in the act includes any hybrids of *P. maxima* produced through laboratory technology. The Act is currently being rewritten. Other pearl oysters, such as *P. margaritifera* (Lamarck 1819), are regulated under the Fish Resources Management Act 1994. The industry is also regulated by a number of acts that deal with items such as marine safety, employment conditions, etc, which are not considered in this study. Under the Australian Commonwealth government's Environmental Protection and Biodiversity Conservation Act 1999, a fishery must be certified as environmentally sustainable by the Commonwealth Department of Environment and Heritage. This has been done for the maxima pearling industry. A copy of the assessment application and determination are available at <http://deb.gov.au/coasts/fisheries/wa/pearl/index.html>. Whereas culture and management methods are similar, the other species are not discussed in this study. The major fisheries regulations for *P. maxima* are described later.

Pearl oysters caught in the wild are seeded with a nucleus at sea in laboratory type conditions on board specially built vessels, then grown out in controlled sea lease areas for 2 years to produce cultured pearls. The wild stock of pearl oysters has thus been the basis of the industry. Several standard fisheries management procedures protect the stocks and ensure continuity of supply. Taking of pearl oysters for seeding is currently controlled by a quota system (total allowable catch is 572,000, but can be varied as

necessary) and additional measures, including size limits. Each operator has an annual quota of live pearl shell. In addition, the animals must be collected from specified zones within the fishery (Fig. 1). The minimum size limit for collection of pearl oysters is 120 mm, when the animals are 3 to 4 years old. There is no regulated maximum size, but in practice individuals are not taken over 160 mm because they are too slow growing to produce high quality pearls. This has a beneficial effect in helping to maintain the breeding stocks because the larger animals are females. Maximum sizes may be specified for particular areas of the fishery (e.g., Exmouth Gulf). Catch and effort data must be provided to DFWA on each dive made during the collecting season. Details are logged using square blocks of 10 nautical miles divided into subblocks of squares with sides of 2.5 nautical miles.

Pearl oysters are seeded after collection and held on the pearling grounds for a period of about 3 months before they are transferred to the farm leases. This allows the animals to recuperate after the stress of being collected, transported to the holding areas and having the nucleus inserted. After the nucleus is inserted, the shells are held in areas separated from those of other operators and areas being fished. Farms are also separated from each other, usually by 5 nautical miles as a counter disease method. However, if the licensee of an existing farm agrees, a new farm can be established as near as 2 nautical miles (FDWA 1997a). Additional reasons for having a clear separation between operators include providing each farm with opportunities for expansion and security of their equipment and pearl oysters.

In recent years hatchery-grown spat have been increasingly used to supplement wild stock. This provides a mechanism for

enlarging the industry in a controlled manner, ensuring a steady supply of stock and in the future potentially reducing costs of obtaining pearl oysters for seeding. Several hatcheries are now in operation. They are all subject to a stringent translocation protocol developed by DFWA in liaison with industry (FDWA 1997b). The hatchery technology provides increased potential for mixing genetically distinct populations during culturing. Johnson and Joll (1993) examined the genetic structure of *P. maxima* collected from 5 widely separated areas: Exmouth Gulf and Cape Bossut, Western Australia; Flat Top Bank and Oxley Island, Northern Territory and Thursday Island, Queensland. Most of the variation found was clinal between western and eastern populations, but comparisons between adjacent pairs of samples usually showed significant genetic differences. This includes the two locations in the Northern Territory that were only 320 km apart. Western Australian samples showed little subdivision over the 800 km from Exmouth Gulf to Cape Bossut. Johnson and Joll (1993) suggested that stocks are in general highly divided in northern Australia but that there are also substantial connections that occur in Western Australia over long distances. The 80,000 to 100,000 *P. maxima* transported annually from Western Australia to farms in the Northern Territory do not seem to have affected adjacent natural populations.

The Western Australian Department of Conservation and Land Management administers several types of marine reserves, and a formal assessment process is undertaken for any application for a pearling lease in a marine reserve. The decision on whether to grant lease approval in a marine reserve rests with the Minister for the Environment, not the Minister for Fisheries. The management areas are:

- Marine nature reserves are set aside for the protection of flora and fauna. Pearling activities are not permitted.
- Marine parks. A series of management zones is established in each marine park to determine the activities that can be undertaken in each zone. Pearling activities may be undertaken in general use zones and some special purpose zones but not in sanctuary and recreation zones.
- Marine management areas allow a broader management approach in the marine environment. Pearling activities are permitted.
- Land reserves include nature reserves, conservation parks and national parks. Land-based pearling activities are not considered to be compatible with the purposes and objectives of the land reserves and are not allowed.

METHODS USED BY THE FISHERY

Background

In 2004 there were 16 operators in the pearl industry in Western Australia, with locations from Exmouth Gulf to the Kimberley. Pearl oysters collected in Western Australia are also used to produce pearls at growout areas in the Northern Territory. Because of differing geography and size of the individual operations, there are differences in the approaches used to produce pearls, but all share common features. The techniques outlined later are generic for the industry, and may be modified by individual operators to adapt to local conditions.

During the late 1970s and early 1980s serious mortality of pearl oysters occurred in the transportation phase of the industry. The mortality was attributed to the bacterium *Vibrio harveyi*, which

Prepared by Department of Fisheries GIS June 2005

Figure 1. Pearl Oyster (*Pinctada maxima*) Managed Fishery.

occurs naturally in the marine environment, including the water column, in sediments and in the guts of marine animals. The mortality occurred after transportation of the pearl oysters from collection areas to the lease sites. Instead of the usual 10% to 20% mortality, losses on lease sites were up to 80%. Surviving pearl oysters developed deformed nacre and were useless for half pearl or mother of pearl production. Poor water circulation and accumulations of mollusk feces on the bottoms of the tanks in which the oysters were transported were found to allow the number of bacteria to increase exponentially during transport. The possibility was also raised that circulation was not as effective on culture rafts as on long lines, and bacterial densities were higher. Whereas other infectious agents or causative factors could have been involved, it was concluded that pearl oysters were weakened during the low temperatures of winter, and they became infected when they came into contact with high bacterial concentrations (Wolf & Sprague 1978, Pass & Perkins 1985, Dybdahl & Pass 1985, Pass et al. 1987, 1988).

The mortality experience has made the pearling industry operators acutely aware that they are dealing with live animals that must be treated properly if high quality pearl production is to be achieved. A number of changes were made to improve treatment of the animals. The various processes are now staged to allow the animals to recover from each procedure (collection, transportation, seed implantation, etc.) before the next stage is attempted. Water circulation during transportation has been improved considerably, and the water in tanks is now exchanged about every 10 min. High-density raft culture has ceased and been replaced with long line techniques that use a lower stocking density.

The pearl industry makes use of a natural phenomenon that occurs in shelled mollusks. Shells produced by mollusks are a mixture of an organic matrix that provides the shape and structure and calcium carbonate that is the actual hard shell material. As a protective mechanism, many species secrete calcium carbonate around a foreign object that becomes lodged in their tissues. This seals the object off from the tissues, rendering it inert to the mollusk. The animal continues to secrete additional material onto the foreign object over time as it secretes additional shell. Many species of bivalves in a variety of groups, and indeed even some gastropods, produce pearls naturally. Because of their high quality, marine bivalves of the family Pteriidae produce most commercial pearls; some are also produced by freshwater species.

Because foreign objects, which lodge in tissues, vary considerably in shape and size; natural (keshi or seedless) pearls tend to be irregular in shape and lustre. Cultured pearls are produced by placing an inert foreign object into a pearl oyster so that it is completely surrounded by mantle tissue inserted in the gonad. The pearl oyster secretes shell material that seals the nucleus completely from the remainder of the body. Over time the animal continues to add layers to the pearl, continually enlarging it. The most common type of nucleus in use at present is made from the shells of freshwater bivalves from the Mississippi River of the United States, but there is an active search by the industry for an alternative source of nuclei.

Inserting a hollow plastic shape between the tissues of the animal and the shell of a pearl oyster in its final year of production makes half round or mabe pearls. The animal secretes shell over the foreign material, resulting in a half globe shape that is continuous with the remainder of the interior of the shell. Mabe pearls are large, with a thin covering of calcium carbonate over the base that had been inserted into the animal. All parts of the animal are

used after an individual oyster produces its final pearl: pearls are harvested, the shell is sold for mother of pearl, and the adductor muscle for edible meat.

Obtaining Wild Caught Pearls

Harvesting of wild pearl oysters occurs from Cape Leveque to Exmouth Gulf, with most collected off Eighty Mile Beach (Bowen 1991). Stocks of commercial quantities of animals at fishable depths (i.e., safe diving depths of <20 m) were surveyed between Broome and the Lacepede Islands in the 1980s (Penn & Dybdahl 1988). Other industry-based surveys have been made in other areas and are available to the industry but have not been formally published (Bowen 1991).

Sea bottoms on which pearl oysters are common are areas where there are crevices that allow the young animals to settle into a protected environment and a hard substratum for them to attach. The industry recognizes a variety of bottom types and has developed names for each. There are transitional zones between the bottom types. If a boat is traveling at a speed of 1 knot during a 1-hour dive, the total distance traversed will be about 1,800 m and there can be several minor changes in bottom type during the dive.

The bottom is typically a flat basement rock with very little relief. Fine sediment accumulates on it to a depth of a few millimeters, obscuring the underlying rock surface. A variety of organisms attach to the rock and provide the vertical relief up to 1 m off the bottom. There can be a substantial overlap in the fauna on the various bottom types; the type is determined by the dominant species present.

A low, round densely packed ascidian species, which lives attached on the bottom is the dominant species on potato bottom. In areas of heavy potato bottom the ascidians are almost completely dominant. Sponges are the next most dominant group, with a large variety of vase shaped, basket sponges and massive sponges up to 0.5 m high interspersed with smaller sponges of only a few centimeters. A variety of other attached fauna is also present, including sea fans, soft corals and sea whips. Despite the diversity of taxa present, total density is low. A very few corals (*Turbinaria*) are present. Faunal density rapidly decreases in areas where the rock is covered with sediment 2–3 cm deep. Bare sand patches can be interspersed between areas of potato bottom.

Garden bottom has a diverse faunal assemblage dominated by alcyonarian sea whips. Distance between the sea whips is variable, but on average they grow about 1 meter apart. The animals grow rapidly to up to 1 meter in height and quickly become encrusted with a variety of organisms, some very colorful, so the bottom does in fact resemble a garden. Sponges and other small encrusting organisms grow on the sea whips. Other than sea whips, a variety of sponges is present on the bottom. Ascidians are present, but are a larger species than that found on potato bottom. Other fauna present includes soft corals, sea pens and crinoids. No hard corals are present.

Whereas potato and garden bottoms dominate in the fishing area, several other bottom types are recognized by the industry, including collar, asparagus, etc. All share the common features of being located on a bottom with underlying rock that are inhabited by a wide variety of invertebrates. None of the habitats are in ecologically sensitive areas such as seagrasses, coral reefs or mangroves, which lack commercial quantities of pearl oysters.

The pearling vessel is a boat up to about 35 m long. Some of the modern vessels are custom made for the pearling industry,

others are modifications of existing boats. To save costs there has been a recent trend for the modern vessels owned by one company to be contracted to also collect pearl oysters for the smaller companies and all gain from economies of scale. The boat crew is usually from 10–12 people, including the skipper, engineer, deckhands, cook(s) and six divers. Booms are extended outward from each side of the vessel during the fishing for pearl oysters. On an average boat, three weighted ropes are hung vertically from each boom to a height of about 1 m off the bottom. There are thus six divers working at a time on the boat. A Morse code type of signal system is used by the chief diver to communicate with the crew on the boat, and control the boat speed, direction, height of the weights and divers, etc. On the rare occasion the weight strikes the bottom, the boat is signaled and the weight is raised. Not only does this practice prevent damage to the bottom, but if the weight is not raised it clouds the water, preventing the diver from fishing efficiently. A large bag near the weight is used to store pearls after they are collected. A good diver collects an average of 250 pearl oysters per day. The areas where pearls are collected are subject to extreme tidal ranges (≤ 9 m), and consequently have very strong tidal currents. Diving is too difficult and dangerous during the spring tidal periods, and is only undertaken on the neap cycle when currents are substantially reduced and visibility is good. Fishing for live pearl oysters begins in January and continues for up to 5 months. The locations of patches have been logged and are revisited on a regular basis. The boat starts at one side of a patch and moves slowly with the tide across the patch at a rate of about 1 knot. Divers operate on hookah, or air supplied from a surface compressor; oxygen may be used at the end of the dive recompression to increase the rate at which nitrogen is purged from the body tissues of the diver. Each diver wears a smaller neck bag during the dive. As pearl oysters are collected they are kept in the neck bag until it is full. The pearl oysters are then transferred to the larger holding bag at the end of each weighted rope. The divers swim about 1.5 m off the bottom to obtain the maximum field of view. In murky water they swim closer to the bottom but are still off it.

At the end of each of the dives the pearl oysters that have been collected are recovered and measured. Under- and oversize oysters are returned immediately to the sea. As divers are paid only for correctly sized animals, novice divers rapidly learn to select sized animals. Shells are cleaned by simply scraping encrusting organisms off the pearl shell with a knife. A high-pressure hose is then used to wash the shells; no chemicals are used. The pearl oysters are placed in wire frame panels holding six animals each, and every panel is individually tagged to indicate which company has collected the shell and placed in a recirculating tank on board. When sufficient animals have been collected, they are taken to a holding area where they are carefully placed on the sea bottom in a marked area for later usage. The panels are attached at 900 mm intervals to lines, which may be several hundred meters long. Divers inspect the line on the bottom to ensure the pearl oysters are in the proper orientation. The bottom selected in this region is very similar to the fishing ground. Sponges are dominant, but there are also soft corals, sea fans and other fauna present, including some *Turbinaria* corals. The period of up to 2 months that the pearl oysters remain in the holding area minimizes the physiological effect of having been collected and allows the animals to recover before the nucleus is inserted. Additional holding areas are used because the boat works different areas.

Seeding the Pearl Oyster

When they are to be seeded, the pearl oysters are recovered, and a piece of mantle tissue from another animal is inserted into the host oyster gonad along with the nucleus for the pearl. The operation is simple, but delicate. The inserted mantle tissue becomes part of the host oyster's tissues, creating a sac around the nucleus. If the oyster is subsequently used to produce a second pearl, the same sac of tissue is used (Joll 1996). After the operation the animals are returned to the ocean in panels at the holding area, again to minimize stress to the pearl oyster. After an initial recovery period of 7 to 8 days the pearl oyster panels are turned by divers over every 2 to 5 days. The turning helps to develop the sac around the nucleus and prevents the nucleus from breaking out of the tissue. The pearl oysters are x-rayed after 4 to 6 months to determine whether nucleus has been retained and the pearl has started to grow. If the nucleus has been rejected from the animal, the pearl oyster is operated on again in the following year or replaced with a hatchery shell (Scoones 1991, Joll 1996).

Transportation to the Farm

Pearl oysters must be cleared from the holding areas by December 31 of every year. They are transported by boat to the pearl farm usually in the waters north of Broome. During transportation, the animals are maintained in seawater in holding tanks on the vessel with running seawater to keep the animals in as natural water conditions as possible. The water may be coarsely filtered to remove large particles. The rate of flow into the tanks changes the water about every 10 min. No feeding or chemicals are used in the transportation process. Each boat is capable of transporting 20,000 to 25,000 animals on a single trip.

Farming Methods

The pearl oysters in the panels are removed from the holding tanks on the boat at the farm. The tanks are emptied and cleaned using a disinfectant before the boat returns to the holding area to obtain a second load of pearl oysters. After the animals have been transported to the pearl farm they are placed in panels on surface long lines into the ocean for a period of 2 years to allow the pearls to grow. When the pearls have been harvested, as many pearl oysters as possible are reseeded. Approximately 40% to 50% of the animals can be used a second time. Forty to fifty percent of these can be reused for a third time; some individual pearl oysters can be used for up to 8 years.

Two anchoring systems are used to keep pearl oysters in the water at the farm, based on the amount of exposure at the site. Most farms use surface longlines. This has the advantages of avoiding the use of divers, minimizing interactions with large salt-water crocodiles and allowing the use of less skilled workers for routine work. In the longline method, steel pegs are anchored up to 2 m deep in the mud of the sea floor. Longlines with surface buoys are used to provide flotation. Vertical lines with panels containing pearl oysters are hung from the buoys and are maintained well off the bottom to avoid fouling. The lines are at least 100 m offshore and are 20–30 m apart to avoid entangling adjacent lines if one breaks. An average line is 100 m long with panels every meter for a total of 600 pearl oysters on the line. This gives a density of only 0.2–0.3 pearl oysters per square meter. A less common method, the bottom farm, is used in areas of harder bottom in more exposed areas such as Roebuck Bay (Scoones 1991). On these farms gal-

vanized steel bars ("star pickets") are used to hold the panels. Surface floats are used only to mark the locations of the farm.

At the farm, the pearl oysters are removed from the water for several minutes only and mechanically cleaned every 4 to 5 weeks, and more frequently in the wet season when growth of fouling organisms is faster. Cleaning machines that use high-pressure water to remove as much growth as possible have been developed; calcareous encrustaceans may be mechanically scraped off; no chemicals are used in cleaning. Dead shells are removed during the cleaning operations.

Harvest of the Pearls

The temperature of the surrounding seawater has an important effect on the lustre and color of the pearl. These are best in winter, so the pearls are harvested during July and August (Scoones 1991). During harvest, suitable pearl oysters are reseeded with a new nucleus to begin the 2-year process of producing a new pearl.

ASSESSMENT OF ENVIRONMENTAL EFFECTS OF PEARLING

In total, 13 environmental and ecological issues were identified across the *P. maxima* fishery. No high risks were identified during the workshop; risks were ranked as either moderate (23%) or low (77%). Moderate risk rankings included: introduction of disease from seeding; attraction of other fauna and introduction of exotic organisms (Fig. 2). The low risks were: spread of disease; introduction of disease from hatchery; introduction of disease from translocation; impact to protected and endangered species resulting from entanglement; impact of habitat; impact to protected and endangered species attracted to farm lighting; nutrient impacts in sediment; perceived change in water quality; potential for litter; reduction of primary productivity; impact of entanglement of protected species; and introduction of disease from translocation.

Introduction of disease from seeding was considered to be of moderate risk. Three related risks, introduction of disease from hatchery or from translocation and spread of disease, were con-

sidered to be low. The low ratings given to disease risks took into account current strict regulatory controls for minimizing disease risks. As discussed earlier, during the late 1970s and early 1980s serious losses occurred because of *V. harveyi* killing the oysters. The bacterium occurs naturally in the oysters, water and sediments. Crowded conditions and poor handling techniques used at the time placed the oysters under considerable stress, which allowed the bacteria to multiply and cause disease outbreaks. Once the causes were known, handling techniques were improved considerably and the pearl oysters were more widely spread in the growout areas. There is now emphasis in the industry on caring for the pearl oysters and the problem has not recurred. It should be noted that *V. harveyi* was not introduced by the pearling industry, rather the crowded conditions allowed it to spread. There are clear DFWA guidelines for procedures to minimize the possibility of introducing diseases through hatcheries. Also, equipment used in inserting the nucleus into the pearl oysters is sterilized before it is used in a different area.

Attraction of Other Fauna

Saltwater crocodiles might be attracted to the farms because of the lights and food wastes. However, these animals are dangerous, and activities that might attract them to the farms are minimized because of safety concerns. Small fish are attracted to the boats when pearl shells are being cleaned, and feed on portions of the material being removed from the shells. This is an intermittent activity, which occurs in a given spot only once every 3 to 5 wk, and then only in the daytime. The effect is transitory, and there is no longer-term buildup of fish populations.

Introduction of Exotic Organisms is a Major Concern in Australia

Once species become established in a new area they may be free of natural predators and other natural constraints on their populations. In these conditions a number of species have developed into plague proportions, which have caused severe environ-

Figure 2. Risk ranking of impacts from pearl farm activities.

mental problems. Once a species becomes established, it is virtually impossible to be eradicated. The only reported successful eradication of a marine introduction worldwide occurred recently in Darwin Harbour. The mussel *Mytilopsis sallei* (Récluz 1849) was successfully removed from three small artificial boat marinas. The eradication was successful because the marinas use locks to allow vessels to enter and leave. They could be sealed off and chemicals introduced to kill the mussels (and virtually everything else) in the marinas (Willan et al. 2000). The issue of possible introduction of exotic organisms has two components, introductions by the pearling industry and introductions from other sources. The north coast of Western Australia is part of the tropical Indo-West Pacific biogeographical zone, which extends from the east coast of Africa across the tropical areas of the Indian and Pacific Oceans to Hawaii. Many species are widely distributed in the region, and some have ranges that extend over the full range. The north coast of Australia, including the full range of the *P. maxima* pearling industry, is part of the Indo-West Pacific (Wilson & Allen 1987). There are no major distributional barriers on the north coast of Western Australia; species tend to be distributed over the entire area if the proper habitat is available. Because the boats in the pearling industry operate within this zone, there is little likelihood of them introducing a species from overseas or eastern Australia.

The Remaining Potential Effects of Pearling Were all Considered to be Low Risk

Impact to protected and endangered species resulting from entanglement would arise if a protected or endangered species became trapped in one or more of the pearl lines. There are no known instances of this happening in the *P. maxima* industry, but there was a recent case in the black lip pearl (*P. margaritifera*) industry in the Houtman Abrolhos Islands on the west coast of Western Australia where a dead whale was washed ashore entangled in pearl lines. It could not be established whether the whale became entangled before or after death. Such occurrences do occasionally happen in the crayfish industry on the west coast, but there are tens of thousands of pot lines in the water during the 7.5 mo season. Entanglements in the pearl industry are at most very rare. Impact to protected and endangered species resulting from farm lighting is a related potential effect of the pearling industry. Oil rigs off the north coast of Western Australia are known to attract sea birds and turtles at night when their lights are on. However, the rigs have considerable lighting for safety and are worked 24 h a day. The small vessels and shore base farms of the pearling industry use only the lighting necessary for their activities, and are largely darkened for much of the night.

Impact of Habitat

Clearly establishing facilities for the pearling industry has some effect on the habitat. However the farms are small when compared with the vast distances on the north coast of Western Australia. They are also predominantly situated over mud bottom for maximum pearl growth. The major impact is the visual presence of the longlines, which are floating in the water, except for an anchor on each end, which is placed in the mud bottom.

Nutrient impacts in sediment, perceived change in water quality and reduction of primary productivity are three interrelated possible effects of pearl oysters being maintained on the farms for 2 years. To some extent they are contradictory. Possibly nutrient

impacts on sediment and perceived changes in water quality were considered to be a possible result of feces from the pearl oysters and residue from the cleaning process. Pearl oysters are sedentary animals with a low metabolic rate. At a density of 0.2–0.3 pearl oysters per square, there is unlikely to be much feces settling to the bottom. There is material cleaned off the shells every 3–5 wk. Again, the low stocking density of the pearl oysters suggests only a small amount of material is put into the system during cleaning. Portions are actively consumed by fish and the remainder is dispersed as it settles to the bottom. In any event, there is no net increase in nutrients, because the biological material was produced from nutrients already present in the water column. Reduction in primary productivity would occur because of the pearl oysters removing material from the water. Again, the effects would be negligible given the low stocking density of the pearl oysters and the dynamic environment of the north coast, where spring tidal ranges vary from 3–10 m, creating strong currents and considerable water flow.

Potential for Litter (e.g., Plastic Zip Tie Tags, Plastic Bags, Buoys) to Enter Water

The litter issue has 2 components: littering and loss of lines during storms. The industry has been very much aware of basic littering issues and has taken steps to minimize this through a code of practice. The northwestern coast of Australia is cyclone prone, with several storms occurring in an average year. If the storm passes near a pearl farm, lines and their attached buoys and panels are occasionally torn free. In such cases every possible effort is made to recover the panels because of their high value.

DISCUSSION

The studies of Enzer Marine Environmental Consulting (1998) and Jernakoff (2002) examined the potential environmental effects of the pearling (*P. maxima*) industry in Western Australia but used very different techniques. However, both came to the same conclusion, that the environmental impacts of the *P. maxima* industry in Western Australia are small. This is accentuated when one compares the industry to the other two major aquaculture industries in Australia, sea cage farming of Atlantic salmon in Tasmania and southern bluefin tuna ranching in South Australia. Both of these industries involve feeding considerable amounts of food to active fish, creating potential problems with uneaten food and fish feces falling through the nets to the bottom in low tidal areas, where it is broken down by physical and biological processes. These problems do not occur in the *P. maxima* industry, where the pearl oysters filter feed naturally and are stocked at much lower densities in high tidal areas where there is considerable natural water flushing.

The Australian Commonwealth government passed the Environmental Protection and Biodiversity Conservation Act in 1999; the act was gazetted in 2000. Under this act the Commonwealth Minister for the environment must certify that a fishery is operated in an environmentally sustainable manner if the fishery is to export its product from Australia. There was a 4-year period during which the initial applications could be submitted and assessed. DFWA (2002) submitted an application based on Enzer Marine Environmental Consulting (1998) and Jernakoff (2002). The Commonwealth Minister assessed the fishery as environmentally sustain-

able on November 5, 2003. Certification is for a 5-year period, after which a fishery must be assessed again.

In Japan, Yokoyama (2002) provided a clear demonstration of the differential effects of fish and pearl aquaculture. Monthly samples of macrobenthos were collected from a fish farm and a pearl farm in Gokasho Bay from June 1995 to July 1996. The results demonstrated that the community structure of the two sites showed distinct differences with seasonal fluctuations. At the fish farm, azoic conditions were found from July to November. After December, diversity increased markedly through successive recruitments of small-sized species such as the polychaetes *Capitella* sp. and *Pseudopolydora paucibranchiata*, and the amphipods *Aoroides* spp. Macrofaunal density, biomass and species richness peaked from March to April. In contrast, at the pearl farm site, a higher diversity, including larger-sized species, and no clear seasonal fluctuations in abundance were found, and community structure was similar to that at the control site. These results show that there was a large impact on the macrofauna at the fish farm, but little effect on the benthic fauna as a result of pearl farming. Yokoyama (2002) suggested that the difference in the level of organic input between the two sites results in the differences in the dissolved oxygen content of the bottom water, sulfide content of the sediments and, subsequently, the macrobenthic assemblages. It should be noted that environmental effects of fish farming depend on site and management. Felsing and Glencross (2004) showed that macrofauna minimized organic accumulation on the seabed at one site in Western Australia.

There have been few other assessments of the environmental impacts of pearl aquaculture, possibly because of the lack of perceived impacts. The studies that have been undertaken are in agreement with the results of the present evaluation of the environmental effects of pearling in Western Australia. Cheney et al. (1995) examined farming of the Black-lip pearl oyster (*Pinctada margaritifera*) in the Tongareva Lagoon, Cook Islands, where commercial farming began in mid 1993 but found little effect. Abo and Toda (2001) examined the relationship between stocking density of the Japanese pearl oyster, *P. fucata martensii* (Dunker, 1850), and planktonic food density measured as the chlorophyll *a* concentration at Gokasho Bay, central Japan. Food density (as chlorophyll *a*) is determined by the balance among the phytoplankton growth, filtration of pearl oysters and outflow by water exchange. A model was developed, which simulated food density and growth of pearl oysters associated with change in the farming density. The calculated food density and growth rate of pearl oyster were higher when the farming density was lower, whereas the food density and the growth rate were lower when the farming density was higher. During the summer peak of chlorophyll *a*, the concentration was about 7 µg/L in areas of normal stocking density of pearl oysters, compared with about 8 µg/L where the stocking density was reduced by half. Increasing the density of pearl oysters to 7 times the *in situ* farming density decreased the phytoplankton density by three-quarters to about 2 µg/L. The authors concluded that filtration intensified by overcrowded pearl oysters decreases food availability, which then retards the growth rate of the pearl oysters. Their model also suggested that the present farming density of the pearl oysters is appropriate under the food condition of their habitat in Gokasho Bay.

Whereas there have been no reports of environmental damage caused by pearl farms, the opposite may be true: the presence of pearl farms may improve water quality. There have been a number of studies suggesting the use of edible oysters to remediate marine

water conditions. For example, Jones (1999) found that the Australian oyster *Saccostrea glomerata* (Gould 1850) acted as a biological filter in reducing phytoplankton, bacteria, total nitrogen, total phosphorus and total suspended solids by amounts ranging from 5% to 67%. Oyster excretion increased concentrations of dissolved ammonium, nitrate/nitrite and phosphate. However, these concentrations were in turn reduced by absorption by the macroalga *Gracilaria edulis*. Whereas the same benefits could theoretically accrue from the use of pearl oysters, in practice stocking densities used in northwestern Australia would be too low to have much effect. Qian et al. (1996) demonstrated that the growth rates of both *Pinctada martensi* and the red alga *Kappaphycus alvarezii* were higher in a coculture system than when the species were cultured independently. When temperatures were above 20°C the alga used nitrogenous wastes from the pearl oysters. Below that temperature algal growth was inhibited and there was no measurable effect. The authors speculated that the reason for improved growth rates of the pearl oysters was improved water quality.

Gifford et al. (2004) suggested that pearl farms could be used as biological filters in coastal areas with anthropogenic nutrient enrichment and pollution. Pearl oysters are capable of filtering water at rates of up to 25 l h⁻¹ g⁻¹ of dry weight tissue. They extrapolated published information to suggest that a pearl farm of 100 tons of pearl oysters could remove 300 kg of heavy metals and 24 kg of organic contaminants through deposition into the pearl oyster tissue and shell, and that up to 19 kg of nitrogen would be removed per ton of pearl oyster harvested. There would also be substantial removal of bacteria. Gifford et al. (2004) suggested the concentration of heavy metals and other pollutants in the tissues and shells would not be a problem because the material would be disposed of at land sites and would not be used for human consumption. Gifford et al. (in press) tested this hypothesis at a small *Pinctada imbricata* farm in Port Stephens, New South Wales, which produced 9.8 tonnes.yr⁻¹. The farm removed 703 g of metals, 7452 g nitrogen, and 545 g phosphorus. The authors concluded that if production was scaled up to 499 tonnes.yr⁻¹, extraction of nitrogen would equal that being produced by a small sewage treatment plant. Changing the harvest dates of the pearls to coincide with the period of peak condition of oyster tissues would substantially increase material removed from the water column. The suggestion is that pearls produced could be sold to provide funding for the remedial activities and a profit. However, there is no information available on the quality of the pearls that would be produced. The *P. maxima* industry in Western Australia is based on producing high quality pearls in natural conditions. It is doubtful that the high quality could be maintained in polluted areas. Further, the north coast of Western Australia, where the industry is located, has few towns and sources of anthropogenic pollution, so there is no possibility of using pearl oysters for environmental remediation in this area.

As indicated earlier, the possible introduction of marine pest species into Australia was assessed as having a moderate risk. Reasons are provided earlier in the study as to why this risk is considered to be low as a result of pearling activities. On the other hand, species that have been introduced by vessels not associated with the pearl industry may potentially affect the industry, and such introductions could have significant impacts. Whereas not all of the ports on the north coast of Western Australia have been surveyed, there are known to be a number of species that have been introduced. NIMPIS (2005) lists 43 introduced or cryptogenic marine species in Western Australia. Seven of these species are on the

north coast of the state, but the list is incomplete. For example, Jones (2004) records six barnacles as introduced to the Dampier Archipelago. Matsuyama (2003) presented an outstanding example damage, which can be caused by an introduced species. The dinoflagellate *Heterocapsa circularisquama* is a causative agent of red tide. It appeared in Japanese waters for the first time in 1988, then spread rapidly in the coastal waters of western Japan. By 2000 there had been 43 red tides caused by *H. circularisquama*, including 18 that damaged fisheries, including the manila clam *Ruditapes philippinarum* (Adams & Reeve 1850) Pacific oyster *Crassostrea gigas* (Thunberg 1793), pearl oyster *Pinctada fucata*, and the blue mussel *Mytilus galloprovincialis* Lamarck, 1819. Economic losses in shellfish aquaculture by direct killing of marketable products were estimated to be at least 10 billion-yen in the last decade; at current exchange rates this is approximately one hundred million US dollars. *Heterocapsa circularisquama* red tides primarily affect bivalve aquaculture. No harmful effects on wild or cultured fish, other marine vertebrates or any public health hazard have been recorded. This is a tropical species, which could potentially cause substantial effects to the pearl industry if introduced into Western Australia.

ACKNOWLEDGMENTS

The authors thank the following people and organizations that have generously provided time and information during the two

studies: Mark Alexander, skipper, and crew of the Paspaley Pearls vessel *Clare*; Dr Dave Mills, Paspaley Pearls; Peter Bergsma and Serena Sanders, Arrow Pearls Pty Ltd; Mick Buckley, John Kelly and Brett McCallum, Pearl Producers Association; Mel Carrington, Shina Gugerl, and Neil Marston Maxima Pearls; John Carroll, Fremantle Paint Suppliers; Nick Duyst, Broome Pearl Hatchery; Jennie Carey and Dr Chris Simpson, WA Department of Conservation and Land Management; Dr Jim Penn, Andrew Bartleet, Heather Brayford Robin Clarke, Colin Chalmers, Dr Rick Fletcher, Ross Gould, Vicki Gouteff, Jo Bunting, Dr Kim Freidman, Greg Finlay, and WA Department of Fisheries; Ben Hollyock and Craig Manning, WA Department of Environmental Protection; Brian Martin, Harbour master, Broome; Rick Scoones, Rick Scoones & Associates; Astrida Mednis, Environment Australia; Harriet Paterson, Sustainable Fisheries Office, Conservation Council and Owen Bunter, MG Kailis. The following PPA member companies responded to the EMS gap analysis questionnaire: Australian Sea Pearls Pty. Ltd; Broome Pearls Pty. Ltd; Cygnet Bay Pearls; Exmouth Pearls; Hamaguchi Pearls; Paspaley Pearling Co; Pearls Pty Ltd; Morgan & Co; and Roebuck Pearl Producers. This project work was funded in part by financial or support-in-kind contributions from the following bodies: Fisheries Research and Development Corporation; WA Industry Development Unit; Pearl Producers Association and International Risk Consultants.

THE ROLES OF BACTERIA AND MICRO AND MACRO ALGAE IN ABALONE AQUACULTURE: A REVIEW

SABINE DAUME

Research Division, Department of Fisheries Western Australia, PO Box 20, North Beach,
WA 6920, Australia

ABSTRACT Abalone aquaculture is dependent on cultured algae to induce larval settlement and as a food source for the early life stages of abalone until formulated feed or macroalgae such as *Macrocystis* sp., *Porphyra* sp. and *Ulva* sp. are introduced into the growout system. In the natural environment, abalone larvae settle on coralline red algae, which provide one of the strongest and most consistent settlement cues available for abalone larvae. However, propagation of coralline red algae is not practical commercially. Abalone farms in Japan successfully settle abalone larvae (*Haliotis discus hannai*) on the green alga *Ulva* sp. *U. lens* also proved to be suitable to enhance settlement of cultured southern Australian abalone species (*Haliotis laevis*, *H. rubra*). Most abalone farms in Australia are now growing *U. lens* for that purpose. *U. lens* is easy to culture, no specific facilities are needed and the alga can be grown on PVC settlement plates in commercial nursery tanks. However, *U. lens* has limited value as a feed for young postlarvae. Instead, cultured diatoms can be added after larvae successfully settle and start feeding. Juvenile abalone (>3 mm in shell length) can consume *U. lens* and grow rapidly on this alga. Diatom cultures and biofilms developing on settlement plates are not axenic and the role of bacteria in early postlarval feeding is poorly understood. It has been suggested that bacteria may perform metabolic activities in the undeveloped gut of young postlarvae. At later stages of the nursery phase it becomes increasingly difficult to maintain adequate feed on the plates and this is still regarded as a significant bottleneck for the abalone aquaculture industry. Recent investigations have indicated that sporelings of macroalgae like *Ulva* sp. or diatoms that can provide more biomass may provide a suitable additional food source for juveniles (>3 mm in shell length).

KEY WORDS: abalone, abalone eggs, antibiotics, algae, bacteria, diatoms, growth, larval quality, lipids, settlement, *Ulva* sp., *Ulva* sp.

INTRODUCTION

Abalone fisheries (*Haliotis* spp.) produce high value, export-orientated products with about 50% of the world supply being provided by Australian fisheries in 1999 (Gordon & Cook 2001). The worldwide catch from abalone fisheries has declined by about 30% over a 10-year period from ca. 14,000 mt in 1989 to 10,000 mt in 1999, and consequently the interest in aquaculture products has increased substantially. The world production of abalone from aquaculture in 1999 was approximately 7,775 tonnes (Gordon & Cook 2001). Future production from the numerous farms and sites established, under construction or approved in several countries including Australia, could be even more substantial if the technology is improved.

In an aquaculture environment, abalone larvae are produced by spawning recently collected wild broodstock, or wild or farmed abalone broodstock that have been held in conditioning systems for extended periods. The nonfeeding larvae have a short larval phase (e.g., 7 days at 17°C for *Haliotis rubra* Leach and *Haliotis laevis* Donovan). When larvae are ready for settlement they actively seek a suitable surface. In the natural environment, abalone larvae settle on coralline red algae (Shepherd & Daume 1996); however on farms the surface is typically vertical, spaced plastic plates that have been colonized by a variety of different algal species. Abalone aquaculture in most countries is dependent on cultured algae at least for the early life stages, to induce larval settlement and as a food source for postlarvae and juveniles, until formulated food is introduced into the growout system. As provision of algal supplies decline, the juveniles may be weaned onto formulated foods. They can be transferred to various land-based tanks or sea-based systems (Freeman 2001). In several countries around the world (e.g., South Africa) even the growout depends

solely on algae; macroalgae that are harvested from the ocean are fed to the abalone in specialist growout systems. A large component of the cost of producing juveniles is the provisioning of live food in a manner suitable for a grazing herbivore. This review examines the roles of bacteria, micro and macroalgae during the nursery phase of abalone aquaculture and emphasizes research conducted by the author with postlarval and juvenile *H. laevis* and *H. rubra* in Australia. It complements earlier reviews by Roberts (2001) on larval settlement and by Kawamura et al. (1998c) on postlarval growth and survival by highlighting the applicability of bacteria and algae for commercial abalone hatcheries and nurseries. Their roles are considered in the context of the main areas of research undertaken to improve juvenile production efficiency: (1) presettlement larvae quality; (2) larval settlement; (3) dietary requirements for postlarvae and juveniles.

Pre-settlement Larvae Quality

Previously wild abalone broodstock that feed on a range of macroalgae have been the main source of gametes for commercial abalone hatcheries. Selection of broodstock is mainly based on gonad size and appearance (Litaay & De Silva 2001), with abalone judged to be ready for induced spawning and have mature eggs based on the amount of swelling of the gonad. However, animal selection based on these criteria shows variable results in spawning success and produce offspring with large variability in larval and postlarval survival. More recently there has been greater commercial and research interest in conditioning captive and farmed broodstock using macroalgae or formulated foods (Grubert & Ritar 2003, Daume & Ryan 2004a, Freeman et al. this volume).

Lipids and protein in abalone eggs are known to fuel the development and metamorphosis of the larvae (Jaekle & Manahan 1989a, 1989b, Litaay et al. 2001). Nelson et al. (2002) demonstrated that variations in lipid content and fatty acid profile of the digestive gland coincided with variation in their macroalgal diets

and are related to seasonal temperature fluctuations. Biochemical variation in the diet may affect the composition of the eggs and ultimately larval performance. However studies of changes in biochemical composition such as fatty acids in abalone eggs are scarce. Litaay et al. (2001) demonstrated changes in biochemical composition during larval development. Recently, Daume and Ryan (2004a) showed high variability in proximate biochemical composition and fatty acid profiles of abalone eggs between batches derived from conditioned and wild broodstock as well as between two consecutive spawning seasons. The relative proportions of some PUFAs in the broodstock diets were reflected in the eggs and varied between batches of conditioned and wild broodstock, indicating that formulated diets designed to maximize growth rates are not necessarily adequate to maintain viable, high quality eggs and larvae from captive broodstock.

Other factors that can influence the quality and success of larval culture are opportunistic pathogenic bacteria that can bloom and cause deformities in and collapse of whole larval batches under potentially stressful commercial growing conditions. Many abalone hatcheries are using antibiotics like oxytetracycline prophylactically. Similarly they may be used in research projects. Roberts (2001) suggested using antibiotics to eliminate bacterial interference in settlement assay systems. Apart from the general problem of development of antibiotic resistant strains of bacteria in hatcheries, problems have been reported with certain antibiotics when used with abalone during larval rearing or settlement assays. Streptomycin at low doses of $5 \mu\text{g mL}^{-1}$ was toxic to *Haliotis diversicolor* (Bryan & Qian 1998). Emitine caused abnormal loss of velum that could have been confused with metamorphosis (Fenteany & Morse 1993).

An experiment conducted to assess the effect of two antibiotics (Ampicillin and Kanamycin at $50 \mu\text{g mL}^{-1}$) on the settlement of *H. rubra* revealed no difference in settlement rate between treated and untreated settlement substrate (Table 1). In this experiment 3 algal settlement substrata were tested (*Navicula cf. jeffreyi*, *Ulvella lens*, *Sporolithon durum*) and compared with a negative control (plastic square of commercial settlement plate without any algal growth) all with and without antibiotics. The ratios of settlement rates between treated and untreated substrates did not change over time. In addition, the difference in settlement preferences between specific substrates remained the same regardless if antibiotics were used or not. The antibiotics were initially effective as indicated by the higher survival of swimming larvae (in water column) in control jars treated with antibiotics. However, the settlement rate was

not higher in the antibiotic treatment, indicating that unfit larvae might survive if treated with antibiotics but they do not settle successfully. This result questions the need and usefulness of antibiotics in abalone hatcheries. Further studies are needed to assess the effects of other antibiotics and earlier treatment with antibiotics (e.g., during larval rearing). However, alternatives like probiotics should be investigated to enhance larval survival safely.

Many antibiotics, including Kanamycin and oxytetracycline, work by inhibiting or interfering with the protein biosynthesis by targeting the bacterial ribosomes. The close similarity between bacterial and mitochondrial ribosomes makes the latter (present in all cells of the "treated" organisms) a potential target (Hart 2004). Inhibition of mitochondrial protein synthesis or injuries in mitochondria of the treated organism have occurred and can lead to various dysfunction; any cell type or tissue with a high aerobic energy requirement is more likely to be affected when this organelle is injured (Hart 2004). The effects of antibiotics on abalone larval settlement and postlarval performance however are not well understood. The knowledge we have from other systems, however, warrants extreme caution and highlights the danger of introducing other, potentially detrimental factors. These may not be obvious initially but may manifest themselves at later stages of larval or postlarval development.

Larval Settlement

The term "settlement" in this review describes the permanent attachment of abalone larvae to the substrate after shedding of the velum to complete metamorphosis. In the natural environment, abalone larvae, like many other invertebrate larvae, settle on coralline red algae. Daume et al. (1999a) revealed that settlement of *Haliotis laevigata* larvae in response to three nongeniculate coralline red algae is species-specific. In that study the frequency of occurrence of epiphytic bacteria and diatoms was assessed on all coralline red algal species tested. However, no significant correlation was found indicating that the settlement induction is algal in origin. The authors concluded that bacteria and diatoms may influence the settlement response of abalone larvae but they are not the main driving force. Roberts (2001) referred to some of his unpublished work and stated that bacteria can induce abalone larval settlement but that the response is slow, taking 1 week to reach 50% metamorphosis. In contrast, very rapid settlement was reported in small-scale laboratory experiments through the use of the coralline red alga, *Sporolithon durum*, with the maximum rate

TABLE 1.

Percentage settlement of *Haliotis rubra* on different settlement substrates (*Ulvella lens* and *Navicula cf. jeffreyi* and a negative control), with and without antibiotics, as well as *Sporolithon durum* (positive control) after 24, 48 hours, % settled and survived up to 1 week and % of larvae in water column after 1 week ($n = 6 \pm \text{SE}$). Data are from Daume (2003).

Species	Antibiotics	% Settlement 24 Hours	% Settlement 48 Hours	% Survival Up to 1 Week	% in Water Column After 1 Week
<i>Ulvella lens</i>	–	30 ± 8.1^a	35 ± 7.6^a	12 ± 1.5	0 ± 0
<i>Ulvella lens</i>	+	22 ± 4.4^a	36 ± 5.3^a	17 ± 1.1	5 ± 1.6
<i>Navicula cf. jeffreyi</i>	–	5 ± 1.4^b	3 ± 2.0^b	4 ± 1.2	8 ± 3.5
<i>Navicula cf. jeffreyi</i>	+	0.3 ± 0.3^b	1 ± 0.3^b	2 ± 0.3	30 ± 4.2
Control	–	0 ± 0^b	1 ± 0.6^b	0.5 ± 0.3	3 ± 1.1
Control	+	0 ± 0^b	0.3 ± 0.3^b	0.6 ± 0.3	54 ± 6.7
<i>Sporolithon durum</i>	–	39 ± 3.7	50 ± 4.6	16 ± 2.6	0 ± 0

Means with different superscript letters are significantly different ($P < 0.05$).

being reached after 24 h (Daume et al. 1999a) indicating that nongeniculate coralline red algae are strong settlement inducers. This result coincides with disproportional high numbers of recruits found on *S. durum* in the natural environment (Shepherd & Daume 1996).

Historically, benthic biofilms, consisting of bacteria and mixed diatom species growing on PVC settlement plates, have been used in abalone hatcheries worldwide to induce larval settlement. Diatoms, brought in by the incoming seawater, colonize clear plastic sheets arranged in commercial nursery tanks. This process is unpredictable and larval settlement rates can be low (1% to 10% of larvae) (Daume 2003). In both experimental and commercial systems, to achieve more control and consistency, films dominated by single algal species can be generated (Daume et al. 2000, Daume & Ryan 2004b). *H. rubra* did not respond to films of any diatom species tested, but settled on the nongeniculate coralline red alga *Phymatolithon repandum* (Daume et al. 1999b). In contrast, *H. laevis* settled comparably well on the diatom *Navicula ramosissima* and on the coralline *S. durum*. Roberts (2001) reviewed data on settlement cues including diatoms and other biofilms. Overall it is apparent that coralline red algae provide more consistent and reliable settlement cues, whereas settlement on diatoms can be highly variable. However, propagation of coralline red algae is not practical at a commercial scale.

Abalone hatcheries in Japan successfully settle abalone larvae (*Haliotis discus hannai*) on the green alga *Ulva lens* (Takahashi & Koganezawa 1988). *U. lens* is also suitable for enhancing settlement of both cultured southern Australian abalone species (*H. rubra* and *H. laevis*) (Fig. 1). Most abalone farms in Australia are now growing *U. lens* for that purpose (Daume et al. 2000, Daume et al. 2004, Daume & Ryan 2004b). The earlier study established settlement preferences of *H. rubra* for *U. lens* at laboratory scale whereas the later studies focused on commercial scale experiments. Both species (*H. rubra*, *H. laevis*) showed a clear preference for older rather than for younger *U. lens* (Table 2, Table 3) even with similar percentage cover, indicating that the developmental stage of the alga and not percentage cover *per se* is important in settlement induction (Table 3). Settlement was also significantly higher in the combined *U. lens* treatments (old and young) compared with 2 diatom treatments (*Navicula cf. jeffreyi* and *Cocconeis* sp. demonstrating the suitability of *U. lens* to improve the settlement of *Haliotis laevis* larvae on commercial scale (Table 3). No significant difference between high and low larval release densities was found with *H. rubra* in the nursery (Table 2) confirming earlier findings at laboratory scale with *H. laevis* larvae that settlement of abalone larvae is not gregarious when tested with larvae of the same batch (Daume et al. 1999a). In contrast, settlement was found to be gregarious in response to conspecific postlarvae as young as 7 days (Daume et al. 1999a) and older conspecific juveniles and adults and their grazing mucus is believed to be responsible (Seki & Kan-no 1981, Slattery 1992).

Figure 1. Sequence from settlement cue to potential food items proposed for Australian temperate abalone species, in commercial farming systems, as they grow.

TABLE 2.

Percentage settlement (\pm SE) of *Haliotis rubra* in the nursery 3 days after larval release ($n = 32$). Data from Daume et al. (2004).

Larval Density	<i>Ulva lens</i>	Per <i>U. lens</i> Treatment	Total per Tank
High	Old (18 days 31% cover). Young (4 days 57% cover).	31.9 \pm 7.5 21.7 \pm 6.8	53.6 \pm 5.8
Low	Old (18 days 31% cover). Young (4 days 57% cover).	44.0 \pm 7.3 26.4 \pm 7.6	70.4 \pm 8.7
Average			62.0

Recently alternative systems, to replace live algae as a means of settlement and growing postlarvae, have been proposed in Japan for *H. discus discus* and *H. diversicolor* (Stott et al. 2002, 2003, 2004a, 2004b). In the earlier studies, an alginate gel solution containing micro particulate diets was pasted onto settlement plates. In more recent studies settlement plates are sprayed with a solution of agar and one of the following: dried algal powder (*Spirulina platensis*, *Chlorella vulgaris*, *Undaria pinnatifida*), dried natural diatom powder, formulated diet and two different concentrations of γ -aminobutyric acid (GABA), each with and without antibiotics, and compared with negative (clean plates) and positive (living natural diatom biofilms). In both recent studies there was no significant difference in settlement rates between the microalgae powder treatments and the living natural biofilm but both supported significantly higher rates when compared with the negative control and GABA treatments (Stott et al. 2004a, 2004b). The authors demonstrated that pregrazing of plates by conspecific juveniles covered with microalgal powder/ agar solution enhanced larval settlement significantly (85% vs. 30% on grazed and ungrazed plates respectively). This system shows some potential, however mechanized and cost-efficient ways of spraying the plates need to be developed before it becomes viable commercially.

Dietary Requirements

Post-larval abalone feed on benthic diatoms (Kawamura et al. 1995) and the diatom film on plates also provides the food for growing postlarvae in commercial abalone nurseries. Commercial farms traditionally rely on mixed species of diatoms as a food source throughout the nursery period (settled larvae to 8–10 mm). The film is maintained through passive seeding (new cells are brought in with the incoming seawater), adding nutrients and manipulating the light intensity through shading. Without much control over composition and density of the biofilm species, the results are very inconsistent and often very poor. Isolating particular diatom species and growing them in monoculture before inoculating settlement tanks in the nursery affords greater control. This however has not been embraced by the industry and further investigations are needed to assess the effectiveness in larger scale systems. However, a significant bottleneck experienced by industry is the inability to maintain adequate food (both quantity and quality) on the plates particularly at later stages of the nursery phase. Growth rates of juveniles are influenced by the availability, digestibility and nutritional composition of the algae (Kawamura et al. 1998b, Roberts et al. 1999, Daume et al. 2003).

The Role of Bacteria in Postlarval Nutrition

Diatom cultures and biofilms developing on settlement plates are not axenic and the role of bacteria in early postlarvae feeding

TABLE 3.

Percentage settlement (\pm SE) of *Haliotis laevis* 3 days after larval release ($n = 3$) when given a choice between 4 substrates. Data from Daume and Ryan (2004b).

Treatments	Old <i>U. lens</i> (8 weeks–97% cover)	Young <i>U. lens</i> (6 weeks–82% cover)	<i>Navicula</i> sp.	<i>Cocconeis</i> sp.	Total per Tank
% Settlement	61 \pm 14	14 \pm 1	7 \pm 0.3	5 \pm 0.5	87

and growth is poorly understood. Newly settled postlarvae ingest diatoms but are often not able to digest the cell contents. This suggests that bacteria and the extracellular material produced by the diatoms, present in the biofilm, are a significant source of nutrition for postlarval abalone (Fig. 1). Garland et al. (1985) reported that postlarval *H. rubra* ingested bacteria growing on the surface of coralline red algae. It has been suggested that bacteria may perform metabolic activities in the undeveloped gut of young postlarvae and are able to enhance the digestion efficiency of the host by supplying polysaccharolytic enzymes (Garland et al. 1985, Erasmus et al. 1997). Polysaccharolytic enzyme activity has been reported in day 17 *H. discus hannai* postlarvae (Takami et al. 1998). Sawabe et al. (2003) detected the bacteria *Vibrio haliticol* in the gut of *H. diversicolor aquatilis* and suggested that this bacterium may play a crucial role in converting alginate to acetic acid. As part of the alternative systems proposed by Stott et al. (2002, 2003, 2004a, 2004b), the authors observed that the growth of postlarvae *H. diversicolor aquatilis* fed a formulated diet was reduced when antibiotics were added and suggested that bacteria that assisted in digestion became limiting. In a later study they discovered that 5–10 times more bacteria (including *Vibrio* spp.) were present on plates sprayed with the agar/formulated diet solution. These bacteria could have provided a substantial food source to early postlarvae, which may have contributed to the significantly better growth rates on these plates 1 week after settlement (Stott et al. 2004b). The authors suggest that for recently settled postlarvae, bacteria might be a superior food source compared with diatom and abalone grazing mucus. All these studies indicate that bacteria are ingested and play an important role in early postlarval nutrition and health, but further studies are needed to elucidate their role and contribution.

Food Preferences for Postlarval Abalone

Worldwide, several studies have examined postlarval feeding and growth on different algal species (Ohgai et al. 1991, Ishida et al. 1995, Kawamura et al. 1998a, Roberts et al. 1999). Studies devoted to examining their feeding preferences and growth (Kawamura & Kikuchi 1992, Kawamura & Takami 1995, Kawamura et al. 1995, Matthews & Cook 1995, Kawamura 1996, Takami et al. 1997, Daume et al. 2000, Takami & Kawamura 2003) have shown that food requirements change as abalone grow (Fig. 1). Two to three weeks after settlement, postlarvae become responsive to the “digestibility” of the diatom strains and grow more rapidly on effectively digested strains (Kawamura et al. 1998a, 1998b). Postlarvae 0.8–2 mm in shell length grow ca 40–60 $\mu\text{m day}^{-1}$ on “digestible” diatoms and only ca 15–30 $\mu\text{m day}^{-1}$ on “indigestible” diatoms (Kawamura et al. 1998b). In addition, the diatom cell size, attachment strength, frustule’s strength and postlarval size can influence digestion. In a feeding trial covering the whole postlarval period, Roberts et al. (1999) showed that different diatom food species affected survival and growth. After day 17, postlarvae

grew faster on *Cocconeis scutellum* and *Cylindrotheca closterium*. Both species were most efficiently digested. Transitions in postlarval feeding preferences and growth performances on different algal species are reviewed in Kawamura et al. (1998c).

Alternative Food Sources for all Stages of Nursery Culture

The green alga *U. lens* has limited value as a food for growing postlarvae. Instead, cultured diatoms can be added after larvae successfully settle and start feeding. Seki (1997) reported that growth rates of postlarvae on *U. lens* were improved by the inoculation of cultured diatoms.

Recent studies showed that plates with a low cover of young germings of *U. lens* could be used for settlement induction of Australian abalone species (*H. rubra*, *H. laevis*) and followed with inoculation of the cultured diatom *Navicula* cf. *jeffreysi* to ensure sufficient food for the growing postlarvae (Daume et al. 2000, 2004, Daume & Ryan 2004b). The former study provided crucial information on early development of *H. rubra* and established that growth rates on several diatom species are significantly higher than on *U. lens* at laboratory scale (Fig. 2). In the more recent study, at commercial scale, the type of substrate on which larvae settled, light (which affected the food density) and the density of postlarvae all had very marked effects on growth (Daume et al. 2004). The results also suggest that early growth is important in determining later performance. Daume and Ryan (2004b) investigated settlement, growth, survival and size variability of the abalone *H. laevis* on commercial scale. Both growth rate and size variability increased over time until juveniles reached approximately 5 mm in shell length. Whereas postlarval abalone do not grow well on *U. lens* (Fig. 2), juvenile abalone (>3 mm in shell length) can consume *U. lens* and grow rapidly (80–110 $\mu\text{m day}^{-1}$) on this alga (Table 4).

Figure 2. Early growth of *H. rubra* postlarvae feeding on different algal species. Vertical bars indicate standard error; $n = 4$. Data from Daume et al. (2000).

TABLE 4.

Daily growth-rates ($\mu\text{m day}^{-1}$) of juveniles (*Haliotis rubra*) on plates 52 days after settlement and shell length (mm) 114 days after settlement (mean \pm SE). Data from Daume et al. (2004).

	Daily Growth Rate ($\mu\text{m day}^{-1}$)			Shell Length (mm) 114 Days
	52-64 Days	64-94 Days	94-114 Days	
<i>U. lens</i>				
Old	79.4 \pm 7.7	107.4 \pm 4.2	82.8 \pm 4.2	6.9 \pm 0.2
Young	94.9 \pm 8.4	115.3 \pm 14.8	87.8 \pm 8.2	7.4 \pm 0.2

At later stages of the nursery phase (>5 mm in shell length), it becomes increasingly difficult to maintain adequate food on the plates and this is still regarded as a significant bottleneck for the industry. Recent investigations have indicated that sporelings of macroalgae like *Ulva* sp. may provide a suitable food source for juveniles (see Strain et al. this volume) (Fig. 1). Alternatively, chain forming diatoms, like *Delphineis*, offer a 3-D structure compared with the 2-D structure of nonchain forming prostrate attaching species, like *Navicula* spp. and thus providing more biomass for the growing juveniles (Fig. 1). Kawamura et al. (1995) reported growth rates of 48 $\mu\text{m day}^{-1}$ of *H. discus hawaii* juveniles 1–2 mm in shell length, when feeding on the diatom *Achnanthes longipes*, which has a 3-D structure. More recently, Takami and Kawamura. (2003) found that juveniles 2.8–2.9 mm in shell length grew 100 $\mu\text{m day}^{-1}$ on this diatom species, which was comparable to growth rates achieved on juvenile sporophytes of the macroalga *Laminaria japonica*.

Biochemical Composition and Nutritional Value of Algal Diets

The biochemical composition of microalgae, and therefore their nutritional value to herbivores varies between species (Brown et al. 1996) and is greatly affected by harvest stage, light intensity (Thompson et al. 1993, Brown et al. 1996), nutrient concentrations (Fábregas et al. 1996, Fábregas et al. 1998) and culture methods (Otero & Fábregas 1997). It is known that the biochemical composition of algae can be altered by changing the growing conditions (e.g., Otero & Fábregas 1997, Thompson et al. 1993, Brown et al. 1996). When microalgal cultures are grown in nitrogen-limited media, the protein content of the cells decreases (Enright et al. 1986, D'Souza & Kelly 2000, Daume et al. 2003). Daume et al. (2003) showed previously that juvenile *H. rubra* grew faster when feeding on the diatom *Navicula* cf. *jeffreysi* that was cultured in a

higher nitrate medium. Searcy-Bernal et al. (2003) found that recently settled *H. fulgens* postlarvae grew and survived better under low light (6 μE) conditions, whereas a lower number of cells of the diatom *Navicula incerta* were available in the lower light treatment. The authors suggested that oxygen supersaturation in the boundary layer, particularly in high-density diatom films at high light levels (75 μE), could have caused high mortality in this treatment. In another study, the influence of light intensity on two diatom species (*Navicula* cf. *jeffreysi*, *Cocconeis* sp.) as a food for juvenile *H. laevigata* (3–4 mm in shell length) was tested (Watson et al. 2004). In contrast to *N. cf. jeffreysi*, growth of *Cocconeis* sp. was not inhibited at lower light levels making it a good candidate for culture in shaded nursery systems. Light was more influential in juvenile grazing behavior (photophobic) than food availability. Watson et al. (2005) examined the combined effect of manipulations in light intensity and nitrate concentrations on the nutritional value of the diatom *Navicula* cf. *jeffreysi* when fed to juvenile abalone (*H. laevigata*). Under high light conditions *Navicula* cf. *jeffreysi* was lower in protein and higher in carbohydrates and fat. Juveniles grazed larger numbers of diatom cells when the protein content was low, possibly compensating for the lower protein levels. The authors reported elevated pH levels in higher light treatments and suggested that this could have caused high mortality. These studies indicate that changes in light intensity and nitrate concentration, under which the diatom species are cultured, can have a dramatic effect on growth, grazing rates and particularly survival of postlarval and juvenile abalone. This emphasizes the need for selecting the right light and nutrient level to achieve high value food and conditions for optimal growth and survival of juvenile abalone in commercial nurseries.

This study reviewed three main areas of abalone research associated with abalone hatchery and nursery production. Further studies are needed to find alternatives, such as probiotics, to the use of antibiotics in abalone hatcheries. Alternative cost effective foods, for broodstock and for the latter stage of the nursery still need to be found that will increase larval quality and allow abalone farmers to keep animals on the plates longer and thus reduce weaning mortality.

ACKNOWLEDGMENTS

The author thanks Stephen Ryan, Sylvain Huchette, Ben Long, Peter Crouch, Anton Krisnich, Sascha Brand-Gardner, Rob Day and Bill Woelkerling who were involved in various parts of the work on *H. laevigata* and *H. rubra*, and Greg Maguire for many useful comments.

EFFECT OF THE POLLUTANTS LEAD, ZINC, HEXADECANE AND OCTOCOSANE ON TOTAL GROWTH AND SHELL GROWTH IN THE AKOYA PEARL OYSTER, *PINCTADA IMBRICATA*

SCOTT P. GIFFORD,¹ GEOFF R. MACFARLANE,¹ WAYNE A. O'CONNOR² AND R. HUGH DUNSTAN^{1*}

¹School of Environmental and Life Sciences, University of Newcastle, Newcastle, New South Wales 2308, Australia; ²New South Wales Department of Primary Industries, Port Stephens Fisheries Centre, Private Bag 1, Nelson Bay, New South Wales 2315, Australia

ABSTRACT Pearl oysters (*Pinctada imbricata*) were held in the laboratory and exposed to various levels of the heavy metals lead and zinc and the aliphatic hydrocarbons hexadecane and octacosane for 2 months. Individual oysters were followed over the course of the experiment, allowing specific calculation of total oyster growth (wet weight) and shell growth. Significant reductions in total oyster growth were observed when oysters were exposed to high concentrations (270 µg L⁻¹) of either zinc or lead. Exposure to the aliphatic hydrocarbons had no effect on total oyster growth. High concentrations of lead completely halted shell growth, the first demonstration of pollutant induced cessation of biomineralization in pearl oysters. Conversely, exposure to moderate levels of lead and the long-chain hydrocarbon octacosane resulted in significant increases in shell width growth. The results from this study indicate that *P. imbricata* is relatively tolerant of the selected pollutants and could be deployed within a remediative context in moderately polluted coastal areas.

KEY WORDS: *Pinctada*, oyster, pollution, biomineralization, pearl, metals, shell, aquaculture

INTRODUCTION

The Akoya pearl oyster, *Pinctada imbricata* (Röding 1798), has a broad global distribution and is found in temperate and tropical waters. This species has been farmed in Japan for over 100 y for its small yet lustrous pearls. But Japanese production of high quality Akoya pearls has fallen from 118,000 kg in 1993 to 63,000 kg in 1996, with continuing production declines (Miyazaki et al. 1999). This decline has in part been attributed to deteriorating water quality (Tomaru et al. 2001). It is well known that bivalve molluscs accumulate many pollutants within their tissue and shell, a fact that has led to their use as biomonitors of hydrocarbons (Sericano et al. 1995) and heavy metals (Bourgoin 1990, Phillips & Rainbow 1993) pollution in marine and estuarine waters. Pearl oysters are no exception to this, and have been used as biomonitors of heavy metals (Bou-Olayan et al. 1995) and hydrocarbons (Fowler et al. 1993). Whereas it is known that pearl oysters accumulate hydrocarbons and heavy metals in their tissues on exposure and that these compounds can exert toxic effects on other bivalve molluscs (Kennedy et al. 1996), there is little information regarding the tolerance of pearl oysters to pollutants.

The tolerance of *P. imbricata* to particular pollutants is of further interest because pearl aquaculture has recently been proposed as a coastal remediation technology (Gifford et al. 2004). Pearl oysters have a high filtration rate, concentrate pollutants and nutrients within their tissues, and they yield a valuable product that is not bound for human consumption. However, the success of a pearl oyster remediation system would rely on the profitability of pearling operations to make the coastal remediation commercially viable. Therefore, it is necessary to investigate the oyster's tolerance limits, for both general pearl oyster health and pearl quality.

Relatively little is known about the effects of pollutants on shell biomineralization in molluscs. In the Pacific oyster, *Crassostrea gigas*, exposure to tributyltin results in the production of a gelatinous substance within the shell and shell deformity (Alzieu et al. 1986), whereas exposure of the mussel, *Mytilus californianus*, to barium results in abnormal shell calcification (Spangenberg &

Cherr 1996). In one of the few studies to investigate the effects of dietary pollutant exposure on shell biomineralization, high (500 µg g⁻¹) dietary concentrations of lead resulted in a 25% reduction in shell mass in juvenile garden snails (*Helix aspersa*), yet shell size was unaffected by lead (Beeby et al. 2002). Similarly, transplanted *Crassostrea gigas* exposed to high concentrations of cadmium, copper and zinc in Chesapeake Bay had significantly thinner shells than control oysters (Frazier 1976). High concentrations of cadmium have also been shown to inhibit shell growth in *Crassostrea virginica* (200 µg L⁻¹, Shuster & Pringle 1969) and *Mytilus edulis* (500 µg L⁻¹, Stureson 1978). Exposure of *C. gigas* to lead for 4 months led to significant differences in the amino acid profile of the shells (Almeida et al. 1998). Shell length growth in *M. edulis* is significantly reduced by exposure to the heavy metals zinc, mercury, copper, and cadmium but not lead and nickel (Strömberg 1982), and various hydrocarbon mixtures (Strömberg 1986, Strömberg et al. 1986). Given that high levels of pollutants alter shell production in many species of molluscs, it is possible that exposure to pollutants could alter shell growth in pearl oysters.

This study investigates the effects of pollutants on total growth and shell growth in pearl oysters. The oysters were exposed to either the essential metal zinc or the nonessential metal lead. These metallic pollutants are both common estuarine pollutants arising from urban, industrial and agricultural applications. Oysters were also separately exposed to either of the aliphatic hydrocarbons hexadecane and octacosane, common estuarine pollutants arising from urbanization and recreational and industrial boating. Furthermore, the hydrocarbons were chosen to represent differing hydrophobicity, which in turn has resulted in differing compartmentalization of pollutants between the shell and soft tissue of molluscs in previous work in our laboratory (Walsh et al. 1995). It was hypothesized that high concentrations of lead, zinc, hexadecane and octacosane would reduce both total and shell growth in the Akoya pearl oyster.

MATERIALS AND METHODS

Experimental Design

The experiment was conducted at the NSW Fisheries Port Stephens Fisheries Centre from June to August 2003 according to

*Corresponding author. E-mail: Hugh.Dunstan@newcastle.edu.au

the protocols of the American Society for Testing and Materials (ASTM) E 729-96 (1996) for static renewal tests. Fifty-one individually aerated 8 L aquaria were divided across two large water baths maintained at 22°C for the course of the experiment. Oysters used were from the same spawning batch from the NSW Fisheries oyster hatchery. Each aquarium contained a single oyster, allowing individual changes in oyster physiology to be monitored. After a 48-h acclimatization period and byssal attachment to the wall of the aquarium, exposure to the pollutant commenced. For the metal treatments, exposure was through the addition of sufficient $\text{Pb}(\text{NO}_3)_2$ or ZnSO_4 solution calculated so as to give final concentrations of background +10, 30, 90, 270 $\mu\text{g L}^{-1}$ of Pb and Zn. For the aliphatic hydrocarbons, sufficient pollutant dissolved in chloroform (at a concentration so as to ensure that the maximum concentration of chloroform in any aquaria was 0.2 ml L^{-1}) was added to give the required concentrations of background +30, 90, 270, 810 ng L^{-1} . The chloroform/hydrocarbon pollutant stocks were stored at -15°C and the metal solutions were stored at 4°C for the duration of the experiment.

Water was changed thrice weekly and the oysters were fed daily a mixture of the algae *Chaetoceros muelleri* and *Tabitiana Isochrysis* aff. *galbana* and *Pavlova lutheri*. There were three replicate aquaria for each treatment. A control treatment with three replicates was also run. Replacement water was heated to 22°C prior to water changes and the salinity and temperature were monitored daily. Temperature and salinity throughout the experiment remained within the range $22 \pm 0.5^\circ\text{C}$ and 33 ± 0.5 g kg^{-1} , respectively.

Parameters Monitored

Before commencing, excess moisture was drained from the surface of the oysters and the total oyster mass was determined to the nearest 0.1 g, then shell length and shell width measured to the nearest mm using vernier calipers. After 2 months, the same parameters were measured.

Statistical Analysis

Differences in shell length, shell width and total oyster mass were analyzed using 1-way ANOVA. Normality and homogeneity of variance were verified using Levenne's test and via graphing residuals, and the data were natural log transformed where necessary. The significance level was taken at $P < 0.05$. Posthoc analysis was conducted with pairwise Tukey HSD test. For the Gaussian correlation analyses, as well as testing for normality and homogeneity of variance, a power analysis was also conducted. All statistical analyses were carried out using SPSS v.10.1 and figures were compiled using SigmaPlot v 6.

RESULTS

Total Oyster Growth (Increase in Wet Weight)

No oyster mortalities occurred during the experimental period and all oysters increased in total wet weight over the 2-month period. Oysters cultured in the control treatment increased total wet weight by, on average ($\pm\text{SE}$), $45 \pm 8\%$.

Exposure to the higher concentrations of zinc and lead resulted in reductions in oyster growth as compared with control oysters (Fig. 1a, b). Oysters exposed to the highest experimental lead treatment had significantly reduced growth ($F = 3.94$, $P = 0.036$, Fig. 1a), compared with control oysters. Whereas there was no

significant difference in the total growth of oysters exposed to the highest zinc treatment and control oysters, a significant decrease in total growth was observed for the 270 $\mu\text{g L}^{-1}$ zinc treatment compared with the 30 $\mu\text{g L}^{-1}$ treatment ($F = 5.14$, $P = 0.016$ Fig. 1b).

Exposure to the aliphatic hydrocarbons hexadecane and octacosane at 30–810 ng L^{-1} did not reduce total body mass after 2 months (Fig. 1c, d).

Shell Growth

Exposure of the oysters to 270 $\mu\text{g L}^{-1}$ of lead significantly reduced shell length growth ($F = 5.14$, $P = 0.016$ Fig. 2a) as compared with the control treatment. The mean length of shells actually decreased by $2 \pm 1\%$ (mean \pm SE) because of shell weakening at the distal margin. Visually, shells from oysters cultured in the high lead treatment lacked the imbricate processes at the distal margin evident in oysters grown in other treatments, indicating shell stress (Fig. 3). Although there was no impact on the measured shell length in the 90 $\mu\text{g L}^{-1}$ treatment, Figure 3 shows that these oysters also lacked the imbricate processes. These two highest lead concentrations resulted in shells that were weaker and more brittle than control oysters. Exposure to zinc did not significantly affect shell length growth over the 2-month period (Fig. 2b). Exposure to hexadecane and octacosane at 30–810 ng L^{-1} did not have any significant effects on shell length (Fig. 2c, d).

Shell width growth was significantly greater in oysters exposed to 30 and 90 $\mu\text{g L}^{-1}$ lead, yet significantly decreased in oysters exposed to 270 $\mu\text{g L}^{-1}$ lead compared with control treatments ($F = 4.6$, $P = 0.02$, Fig. 4d). Exposure to the longer chain hydrocarbon, octacosane, also resulted in increased shell width growth (Fig. 4d), but no significant differences to shell width were observed for oysters exposed to zinc and hexadecane (Fig. 4b, c).

Relationships Between Concentration of Pollutants and Shell Growth

For lead, zinc and octacosane, clear associations were apparent between the concentration of the pollutant and the percentage increase in shell width (Fig. 5). Moderate additions of these pollutants above the background level caused increases in the shell width growth. However, exposure to the higher experimental treatments resulted in reduced levels of shell width growth. For hexadecane, there was no relationship between pollutant concentration and shell width growth.

In contrast to shell width, whereas high concentrations of lead inhibit shell length growth, there was no relationship between concentration of pollutant and shell length growth for all 4 experimental treatments.

DISCUSSION

Heavy metals inhibit growth in a variety of mollusc species (Manley et al. 1984, Wikfors et al. 1994, Din & Ahamad 1995, Keppler & Ringwood 2001). In this study, total oyster mass was reduced in *P. imbricata* oysters exposed to high concentrations of lead and zinc. The dose response was not linear, with no obvious effects on oyster growth at 10–90 $\mu\text{g L}^{-1}$ for lead and zinc; this indicates that *P. imbricata* is relatively tolerant of the individual effects of lead and zinc, at least up to concentrations of approximately 90 $\mu\text{g L}^{-1}$. Effects on total oyster mass were observed at the higher concentration (270 $\mu\text{g L}^{-1}$). Typically, the concentration of dissolved lead in low-moderately human impacted estuaries is below 10 $\mu\text{g L}^{-1}$ (Barnes et al. 1982, Dassenakis et al. 1997). As

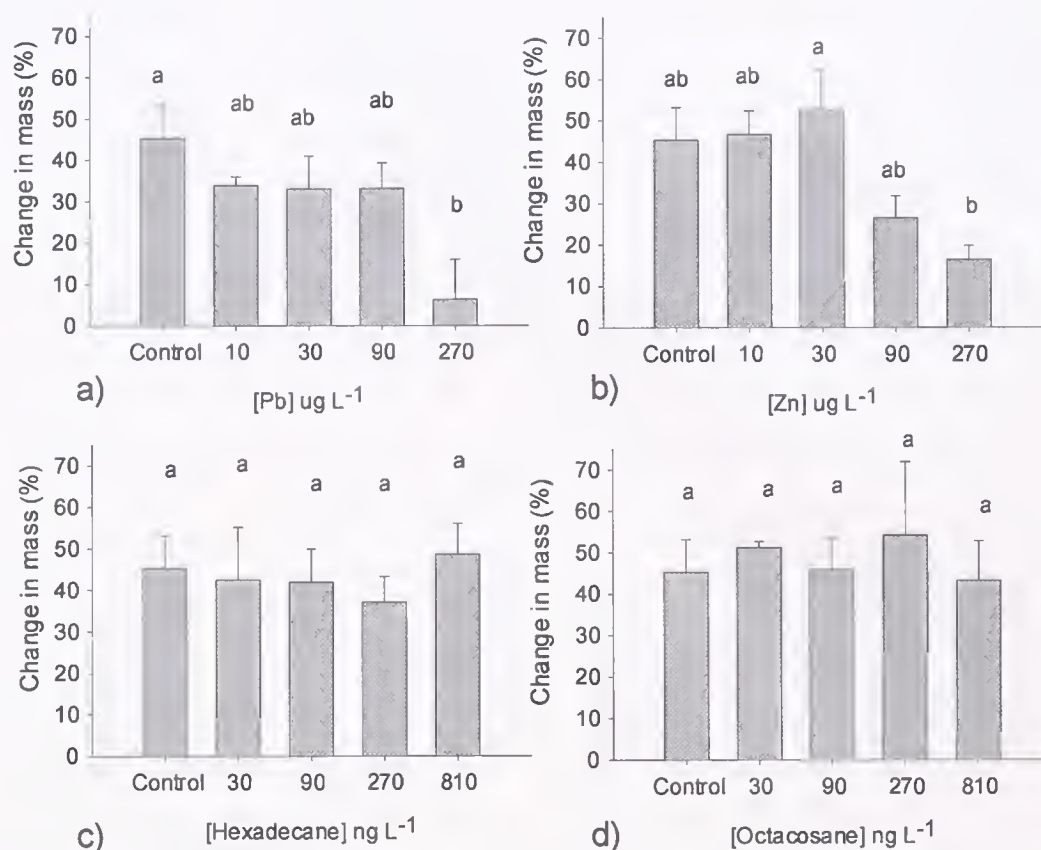

Figure 1. Mean change in mass (%) of *Pinctada imbricata* cultured under five different concentrations of lead, zinc, hexadecane and octacosane. Treatments identified as statistically similar are denoted by identical letters as determined by Tukey HSD pairwise comparison test. Error bars show SE ($n = 3$).

such, this study provides important information on the zinc and lead tolerance limits of the commercially important Akoya pearl oyster. However, caution is necessary in extrapolating these laboratory results to field situations, because possible synergistic or antagonistic effects among pollutants may exist. Furthermore, the potential for size dependent changes of metal impacts on oyster health must also be considered.

Exposure to either of the aliphatic hydrocarbons used in this study did not significantly effect total oyster growth. Organic contaminants are known to adversely affect bivalve molluscs in a variety of ways including reduced feeding (Widdows et al. 1990), induction of stress proteins (Cruz-Rodriguez & Chu 2002), inhibition of oogenesis (Chu et al. 2000) and increased respiration (Widdows et al. 1990). However, most of these studies involve either halogenated hydrocarbons, such as polychlorinated biphenyls (PCB), or polycyclic aromatic hydrocarbons (PAH), with very little toxicological information regarding aliphatic hydrocarbons available. The results from this study indicate that dissolved concentrations of aliphatic hydrocarbons in the high ng L^{-1} range do not impact total growth of *P. imbricata*.

Shell structure of *P. imbricata* exposed to $270 \mu\text{g L}^{-1}$ lead was visibly altered, with a complete lack of imbricate processes (frills) around the shell margin. Little information exists on the effects of pollutants on shell growth (Shuster & Pringle 1969, Frazier 1976, Strömberg 1982, Almeida et al. 1998, Beeby et al. 2002), and this is the first study to investigate the effects of pollutants on biomineralization in an economically important pearl oyster. Lead exposure has previously been shown to reduce shell thickness in the

common garden snail *Helix aspersa* (Beeby et al. 2002), and alter amino acid composition of the shell of *Crassostrea gigas* (Almeida et al. 1998). In our study, shell growth was completely impeded by exposure to $270 \mu\text{g L}^{-1}$ of lead. Shuster and Pringle (1969) reported complete inhibition of shell growth by *Crassostrea virginica* exposed to similar concentrations of cadmium, whereas Strömberg (1982) observed cessation of shell growth in *Mytilus edulis* when exposed to copper and mercury. These results could be because of reduced activity of the enzyme carbonic anhydrase, an enzyme essential for shell and pearl production (Wilbur & Jodrey 1955, Freeman 1960, Miyamoto et al. 1996). Lead has previously been shown to inhibit levels of carbonic anhydrase in both anemones and corals (Gilbert & Guzman 2001), cadmium inhibits carbonic anhydrase in estuarine crabs (Vitale et al. 1999, Skaggs & Henry 2002) and eels (Lionetto et al. 1998), whereas silver, copper and zinc all reduce levels of carbonic anhydrase in crabs (Skaggs & Henry 2002).

Whereas high concentrations of lead significantly reduced shell growth, exposure to 30 and $90 \mu\text{g L}^{-1}$ of lead had the opposite effect, significantly increasing growth in shell width. Whereas active metal incorporation into shell matrix has previously been described (Bertine & Goldberg 1972, Sturesson 1976, 1978, Al-Aasm et al. 1998), this is the first reported case of an increase in shell growth in response to moderate metal challenge. Exposure to octacosane also resulted in a significant increase in the growth of shell widths. In contrast, hexadecane did not significantly increase shell width growth. These results complement the earlier work of Walsh et al. (1995), who observed that longer chain hydrocarbons

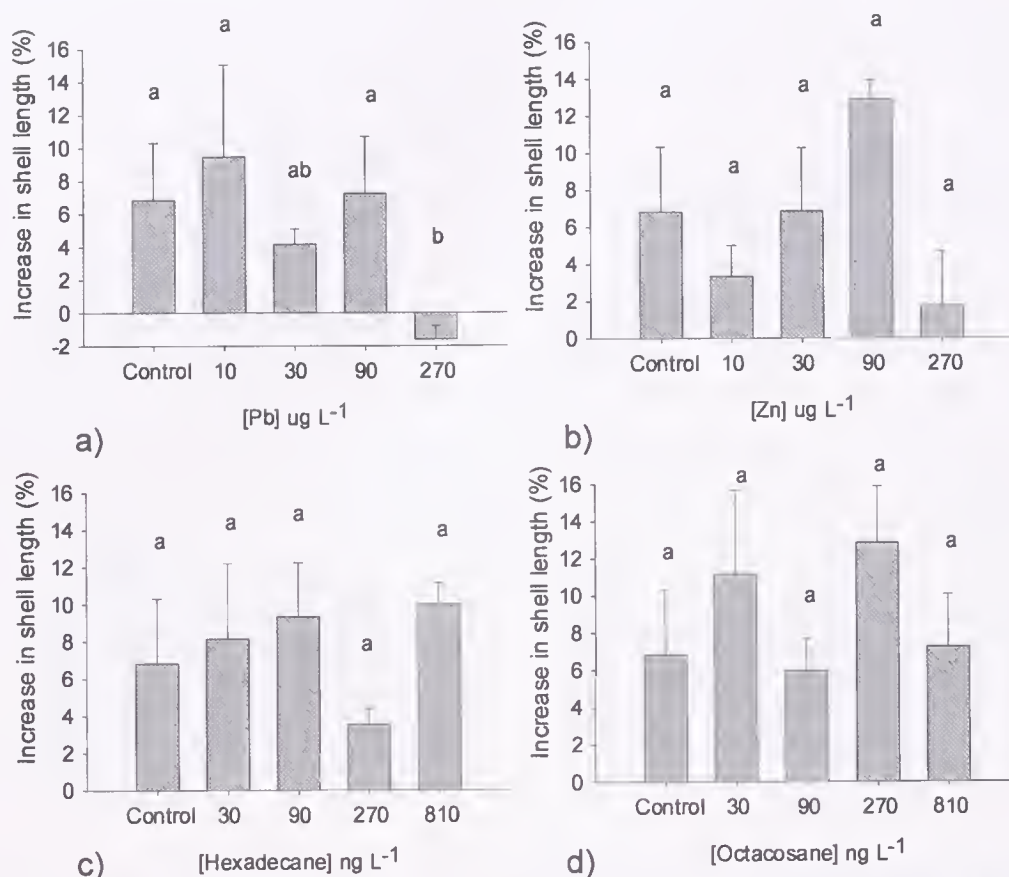

Figure 2. Mean change shell length (%) of *Pinctada imbricata* cultured under five different concentrations of lead, zinc, hexadecane and octacosane. Treatments identified as statistically similar are denoted by identical letters as determined by Tukey HSD pairwise comparison test. Error bars show SE ($n = 3$).

(those compounds resistant to cellular degradation systems) preferentially accumulated in the shell of the gastropod *Austrocochlea constricta*, whereas shorter chain hydrocarbons were preferentially accumulated in the soft tissue of the organism. These authors proposed that the smaller aliphatic hydrocarbons might be more easily detoxified via cellular enzymatic systems within the soft tissue, whereas more hydrophobic and recalcitrant compounds could be actively partitioned into the shell matrix and thereby removing them from metabolically active tissue (and subsequently the food chain). The observed gaussian response of shell width to three of the four pollutants (Fig. 4) tested was consistent with this theory, although this result is highly dependent on the growth of

control oysters and in this experiment the control group consisted of only 3 oysters. Further studies are continuing to investigate the capacity of these animals to partition heavy metal and the more hydrophobic organic pollutants into the shell matrix.

In contrast to the results of this study, Strömberg et al. (1986) observed significant reductions in shell growth of the mussel *M. edulis* exposed to high concentrations of a microencapsulated mixture of n-alkanes. Concentrations used in our study were, however, approximately 1,000 times less than those used by Strömberg et al. (1986) and were the likely cause of the observed differences. Interestingly, Strömberg et al. (1986) found no difference in the effect of the aromatic and the n-alkane hydrocarbon mixtures on shell growth. Typically, aromatics are viewed as being more toxic than aliphatic hydrocarbons (Anderson et al. 1974). Given that very little is known about the effects of hydrocarbons on shell production (Strömberg 1986, Strömberg et al. 1986) further research in this area is clearly warranted.

Recently, pearl aquaculture has been proposed as a coastal bioremediation technology (Gifford et al. 2004). This is because of the fact that pearl oysters have high filtration rates (Pouvreau et al. 1999), concentrate pollutants within their tissue and shell (Al-Madfa et al. 1998, Bou-Olayan et al. 1995), have a high protein content (Suzuki 1957, Numaguchi 1995), are found native in many areas of the world (Colgan & Ponder 2002) and the highly valued pearl product is not bound for human consumption. Because the mechanism of pearl production is similar to that of shell production in the oyster, any effects observed on shell growth would likely be mirrored in pearl formation. Therefore, the inhibition of

Figure 3. Oysters cultured under different concentrations of lead; a) $10 \mu\text{g L}^{-1}$ b) $30 \mu\text{g L}^{-1}$ c) $90 \mu\text{g L}^{-1}$ and d) $270 \mu\text{g L}^{-1}$. Note the imbricate processes (marked in b) are absent around the shell margins for the oysters cultured under 90 and $270 \mu\text{g L}^{-1}$.

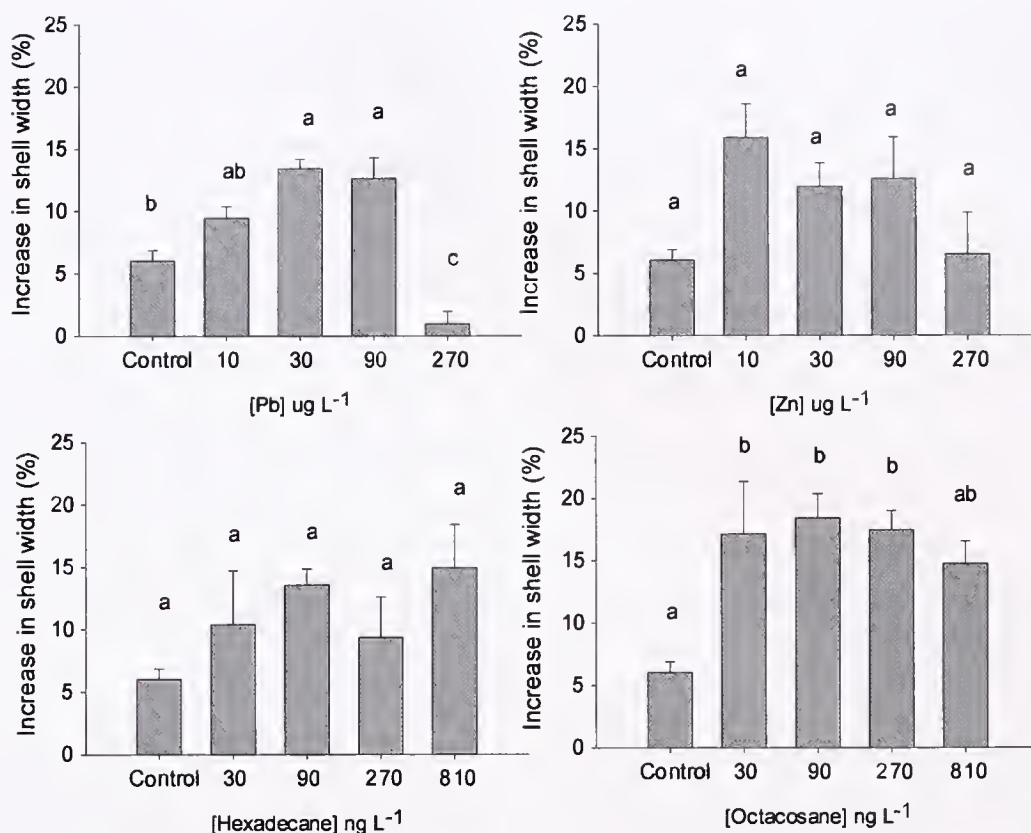

Figure 4. Mean change in shell width (%) of *Pinctada imbricata* cultured under five different lead, zinc, hexadecane or octacosane treatments. Figure 5. Relationships between concentration of pollutant and oyster shell width.

shell growth by high ($270 \mu\text{g L}^{-1}$) concentrations of lead in this study demonstrates that pearl aquaculture would be unlikely to succeed in areas suffering from high concentrations of dissolved lead. However, moderate concentrations ($10\text{--}90 \mu\text{g L}^{-1}$) of dissolved lead had the opposite effect, stimulating shell width growth. Furthermore, whereas high ($270 \mu\text{g L}^{-1}$) zinc concentrations did not significantly effect shell growth, a finding similar to Mai et al. (2003) who found that dietary zinc did not effect biomineralization in the abalone *Haliotis discus hannai*, they did reduce total oyster growth. Therefore, pearl aquaculture would unlikely succeed in areas with high dissolved zinc concentrations. The concentrations of aliphatic hydrocarbons used in this study did not negatively affect any of the measured oyster parameters, and in fact stimulated shell width growth at $30\text{--}270 \text{ ng L}^{-1}$. Therefore careful evaluation of potential sites would be required to balance metal remediation requirements and pearl quality/oyster health outcomes.

CONCLUSION

Exposure to high ($270 \mu\text{g L}^{-1}$) concentrations of dissolved lead reduced total oyster growth in *P. imbricata*. Importantly, high (270

$\mu\text{g L}^{-1}$) concentrations of lead significantly reduced shell growth and altered the visible appearance of the shell, the first demonstrated case of pollutant-impeded biomineralization in pearl oysters. However, intermediate concentrations ($10\text{--}90 \mu\text{g L}^{-1}$) of lead and zinc actually stimulated shell width growth. Exposure to the aliphatic hydrocarbons hexadecane and octacosane had no effect on the total oyster growth. However, exposure to moderate ($30\text{--}270 \text{ ng L}^{-1}$) concentrations of the long chain hydrocarbon octacosane significantly increased shell width growth. The results of this study demonstrate the general tolerance of *P. imbricata* to the pollutants lead, zinc, hexadecane and octacosane.

THE ROE'S ABALONE FISHERY NEAR THE PERTH METROPOLITAN AREA, WESTERN AUSTRALIA

BOZE HANCOCK^{1,2} AND NICK CAPUTI¹

¹Department of Fisheries, Western Australia Fisheries and Marine Research Laboratories, PO Box 20, North Beach, Western Australia 6920, Australia; ²Department of Zoology, University of Western Australia, Nedlands, Western Australia 6907, Australia

ABSTRACT The recreational Roe's abalone fishery is concentrated on easily accessible reefs that adjoin metropolitan Perth in Western Australia. There is a restricted recreational fishing season of 1.5 h a morning, for six consecutive Sundays in November and December each year. The reefs near Perth are also the focus of the commercial Roe's abalone fishery in Western Australia. The recreational catch and effort for each 10 nautical mile section of the Perth fishery is estimated from a creel survey with instantaneous counts, aerial surveys and interviews with fishers, from 1997–2003. Most of the recreational and commercial catches were taken from small areas of the fishery, with approximately 87% of the recreational catch coming from two 10 nm sections, and 98% of the commercial catch coming from these two and one additional 10-nm section. An annual quota of 36 t limits the commercial catch, whereas estimates of the recreational catch increased from 33–51 t between 1997 and 2003. Recreational catch and effort estimates from 1999 on were corroborated by an independent telephone survey, with independent estimates falling within the 95% confidence intervals.

KEY WORDS: Roe's abalone, *Haliotis roei*, recreational catch and effort, commercial catch, volunteer, creel survey

INTRODUCTION

Roe's abalone, *Haliotis roei*, is distributed between the central Victorian coast and Shark Bay on the west coast of Western Australia (WA) (Shepherd 1973). It occupies the low intertidal and shallow subtidal areas of rocky reef adjoining the coast in south-western Australia (Shepherd 1973), and grows to a maximum size of about 120 mm (Wells & Keesing 1990). In the waters near Perth WA, Roe's abalone occupy the low intertidal and subtidal limestone reefs of the mainland and offshore islands. It also occurs on some offshore reefs topped by wave-cut platforms at about low tide level. In areas of favorable habitat, Roe's abalone attains densities approaching 200 m⁻² (Hancock 2004). Densities are highest at the seaward edge of the reef platform because of the settlement of the recruits in this habitat. Densities drop to low levels by about 1.5 m depth on the subtidal cliff at the seaward edge of the reef. Densities decline more gradually shoreward from the outer edge of the reef platform. The mean size of abalone tends to increase subtidally and shoreward from the seaward edge of the reef platform.

WA is the only state with a Roe's abalone fishery, but a feasibility study has been completed in South Australia (Preece et al. 2003). Commercial abalone fishing in the Perth area began in the early 1960s, but was small scale until 1970 when an influx of divers from other states caused a rapid increase in catches (Joll & Penn 1992). In 1970 the first of a complex array of area closures and restrictions on fishing time and daily catch were introduced for the commercial fishery in the Perth area. The Perth fishery is currently described in a series of sections of 10 min of latitude, (i.e., 10 nautical mile [nm] sections). For the commercial sector the Perth Roe's abalone fishery extends from the mouth of the Moore River in the north, to Cape Bouvard to the south (sections 36–43, Fig. 1). From 1992 to 2002 the recreational fishery extended approximately 30 nm further north, to Wedge Island (sections 33–43, Fig. 1). The commercial sector is excluded from fishing in the area around Rottnest Island, and the Cottesloe area of the mainland

coast. These areas remained open to recreational fishers until the closure of Cottesloe in 2003. Rottnest Island was not included in this study, and is not considered to be an important area of the fishery. The area around Penguin Island was closed to recreational fishers from 1996 to 1999, but remained open to some commercial fishing.

Since the summer of 1990 to 1991 the commercial catch from the Perth fishery has varied from 17.7–46.1 t whole weight, compared with a total catch from the state of approximately 108–119 t. During 1997 regulation of the commercial harvest of abalone from the Perth fishery was changed from mainly input-controlled to output-controlled by the removal of restrictions on allowable fishing times, and the introduction of quotas. Quotas were set at 3 t for each of the 12 commercial fishers (36 t total quota), for the period from October 1997 to September 1998 inclusive, reported here as the 1997 season. To align the quota periods for the different abalone managed areas around the state, the Perth season was adjusted to an April to March quota period.

Interest in the recreational fishery increased steadily from the early 1970s. By the early 1980s increasing fishing pressure had led to localized stock depletions and escalating conflict between the two user groups, resulting in a closure of the majority of the fishery for the 1983 season (Wells & Keesing 1989). Since the commencement of fishing in 1984, there has been a series of restrictions on both sectors, including the introduction of a recreational fishing licence in 1992. Since 1995 the season has consisted of 6 Sunday mornings from 7:00 AM to 8:30 AM, starting on the first Sunday in November. The minimum legal size of abalone taken by the recreational sector is 60 mm, with a daily limit of 20. The majority of fishers wade on the reef platform to search for abalone, with a small proportion snorkeling adjacent to the platform. The use of compressed air to collect abalone from the subtidal areas by recreational fishers is not permitted.

Australian abalone fisheries, including the *H. roei* fishery, are currently considered to be operating at sustainable levels; however globally there are cases where high exploitation levels have been a primary cause of the collapse of major fisheries. Notable instances include the collapse of fisheries in California (Tegner et al.

Figure 1. Map of Western Australia, showing the area of the Perth abalone fishery (inset), subdivided into 10 nm sections (enlargement). Boxes indicate the portions of the fishery designed as high usage zone, enlarged in Fig. 2. + indicates the location of the wave recording station.

1992, Parker et al. 1992, Karpov et al. 1998) and Mexico (Guzmán del Prío 1992), with more recent concern for the sustainability of the South African fishery (Tarr 2000, Tarr et al. 2000).

Recreational fisheries are increasingly recognized as making up an important component of the total fishing harvest of exploited nearshore marine populations (Kearney 1995). Although commercial catches are often carefully recorded, recreational catches are not as easily quantified. Consequently there is an emphasis on measuring the recreational catch component of many fisheries. The aim of measuring the recreational catch and effort has generally been: (1) to quantify an important impact on a fished stock, in concert with commercial catch; (2) to address issues of fishery sustainability and (3) to establish a basis for informed debate regarding resource sharing between interest groups (Kearney 1995). Surveys of recreational abalone catch and effort conducted in New South Wales (Worthington et al. 1998) and Tasmania (Lyle & Smith 1998), in New Zealand (Teirney et al. 1997, Bradford 1998) and South Africa (Anon 1998, 1999), have generally concluded that catch and effort are increasing where management restrictions have not been introduced. The recreational component of these

fisheries varies from over 90% in some areas of New Zealand and nearly 50% in South Africa, to as low as 3% in Tasmania.

In the Perth Roe's abalone fishery, where fishers can easily access a substantial portion of the abalone population, the recreational catch is likely to be a particularly important component of the total catch. Because Perth is also the focus of the commercial fishery, providing approximately one-third of the annual commercial catch for the state, understanding the total catch in the Perth fishery is an important component of managing the resource.

The total catch in the Perth area needs to be determined on a scale that is appropriate to the stock structure for the species. The genetic neighborhood of populations in the Perth area has been found to be less than 13 km (Hancock 2000). Therefore, catch and effort information for this intensively harvested species should be considered in units of less than 13 km, or units of semi continuous reef. The finest spatial resolution of the commercial catch records during the period of this study was 10 nm sections of coast. These sections reasonably approximate units of semi continuous reef.

The objective of this study is to: (1) estimate the recreational catch and effort for each 10 nm section of the Perth Roe's abalone

fishery and (2) compare the relative catches of the recreational and commercial sectors over the study period.

This study has been complemented by the development of an independent telephone survey designed to estimate the recreational abalone catches from the whole Western Australian coast. The survey was stratified to provide more detail for the Perth fishery (Hancock et al. 2003). Catch estimates from the Perth area derived from telephone and creel surveys provide a rare opportunity to compare independent recreational catch estimates.

MATERIALS AND METHODS

A methodology for estimating the recreational catch and effort was developed using an intensive examination of data obtained between 1997 and 1999. This technique was then used to obtain estimates for subsequent years as an on-going monitoring program. The development of the estimation procedure is described in detail and results obtained by applying the described technique to data collected from 2000 to 2003 are reported.

Spatial Stratification of the Perth Recreational Fishery

The Perth recreational abalone fishing area has been stratified into zones of high and low usage, based on extensive observations (Fig. 1). The highest levels of utilization are in areas of reef adjoining the mainland shore. Within this range the areas most targeted by recreational fishers have been identified (Fig. 2). The low usage zone is the remainder of the area between Cape Bouvard and Wedge Island (Fig. 1).

Environmental Conditions

For each day of the fishing season the prevailing fishing conditions are likely to influence the distribution of effort and the catch rate of recreational fishers. To quantify fishing condition and enable fishing conditions to be accounted for when estimating effort, a 10-point index was developed, with very good conditions equal to 0 and very poor conditions equal to 9 (Table 1). The fishery operates on the reef platform or shallow subtidal areas of an exposed coastline. Wave and tide height are thus especially important, with minor influence from light level, as determined by cloud and rain. Wave heights were obtained from the Department of Transport "Deep Channel" wave station in section 39 (31°58'40"S 115°41'12"E, Fig. 1). Recordings were divided into wind-driven wave and swell height, based on wave period. On mornings with a dominant easterly (offshore) wind, swell height was used, and on mornings with a dominant westerly (onshore) wind, the sum of swell and wind-wave height was used. Tide heights were obtained from the Department of Transport, Fremantle recording station. Cloud cover and rainfall were obtained from the Bureau of Meteorology, Mt. Lawley station.

Effort—High Usage Zone

Within the high usage zone there were 20 discrete areas from which counts of the number of fishers were taken (Fig. 2). All fishers were visible from raised vantage points within each area. The length of coast adjacent to the 20 areas ranged from 130 m to 895 m, giving a total of 6,924 m of coast in the areas counted, or 60% of the total length of reef which provides suitable habitat for Roe's abalone (11,553 m) in the high usage zone (Fig. 2). Count areas were located systematically throughout each 10-nm section to achieve an approximately even geographical spread of sampling effort, whereas the exact size and position of each area was ad-

justed so that unambiguous start and end points could be described from land and air, using purpose-drawn maps. Count areas represented reefs of high and low accessibility, and greater and lesser usage by fishers.

Department of Fisheries research staff and volunteer fisheries liaison officers (VFLOs) conducted instantaneous counts of the numbers of fishers. VFLOs were instructed to take a minimum of one count of fishers actively engaged in fishing from their area at 7:10 AM (710 count), and encouraged to take 3 or more counts throughout the fishing period. Research staff conducted a count every 10 min from 7:10 AM to 8:20 AM, a total of eight counts for the 1.5-h period. Effort was calculated in fisher minutes for each count area using the research samples and the VFLO samples for which there were three or more instantaneous counts. The VFLO samples were used only if a 710 count was taken, and at least one count was taken from each half hour period between 7:30 to 8:00 AM and 8:00 to 8:30 AM. The calculation of effort can be illustrated by plotting the histogram of instantaneous counts taken during the fishing period at a site, against the time the counts were taken (Fig. 3). The area of the histogram describes the effort in fisher minutes. For the volunteer samples, the area of each bar of the histogram or effort described by each count was determined by the timing of each instantaneous count. This can be described as in the following equation:

$$E = C_1 \left((t_1) + \frac{(t_2 - t_1)}{2} \right) + \sum_{i=2}^{f-2} C_i \left(\frac{(t_i - t_{(i-1)})}{2} + \frac{(t_{(i+1)} - t_i)}{2} \right) + C_f \left(\frac{(t_f - t_{(f-1)})}{2} + (90 - t_f) \right)$$

where E is the effort for the count area on a day in fisher minutes, C is an instantaneous count of fishers, t is the time the instantaneous count was taken in minutes from the start of fishing at 7:00 AM, i indicates the count number for intermediate counts between 1 and f , the final count for the fishing period.

Analysis of fisher participation was initially undertaken using data collected during the 3 years from 1997 to 1999. Counts of fisher participation were taken from a possible total of 20 areas per fishing day, for each of the six fishing days in 1997, 1998 and 1999 (Table 2). There were two kinds of measures of effort during 1997 to 1999, those calculated from the research samples with eight counts per day (41 cases), and those calculated from VFLO samples with three to five counts per day (146 cases). Each type of sample included a 710 count. Table 2 also contains two types of missing values where there were insufficient data to calculate effort for an area on a given day: those for which the available effort information was only one 710 count (58 cases), scenario a; and those for which there was no effort information at all (115 cases), scenario b. The missing values were estimated using two predictive generalized linear models that were developed with the information contained in the 187 research and VFLO samples. The use of volunteer staff limits the ability to prescribe completely the timing and number of counts taken during a fishing day and the areas counted per day, resulting in missing data for some areas.

For the first model, scenario a, the research and VFLO sampling was used to establish a relationship between the 710 count and fishing effort at an area for a given day, after accounting for variables and interactions that may affect this relationship. This model then used the 710 count to predict the missing effort estimate for the 1.5-h fishing period (Table 3). The appropriate predictive model to estimate the effort for scenario b was determined

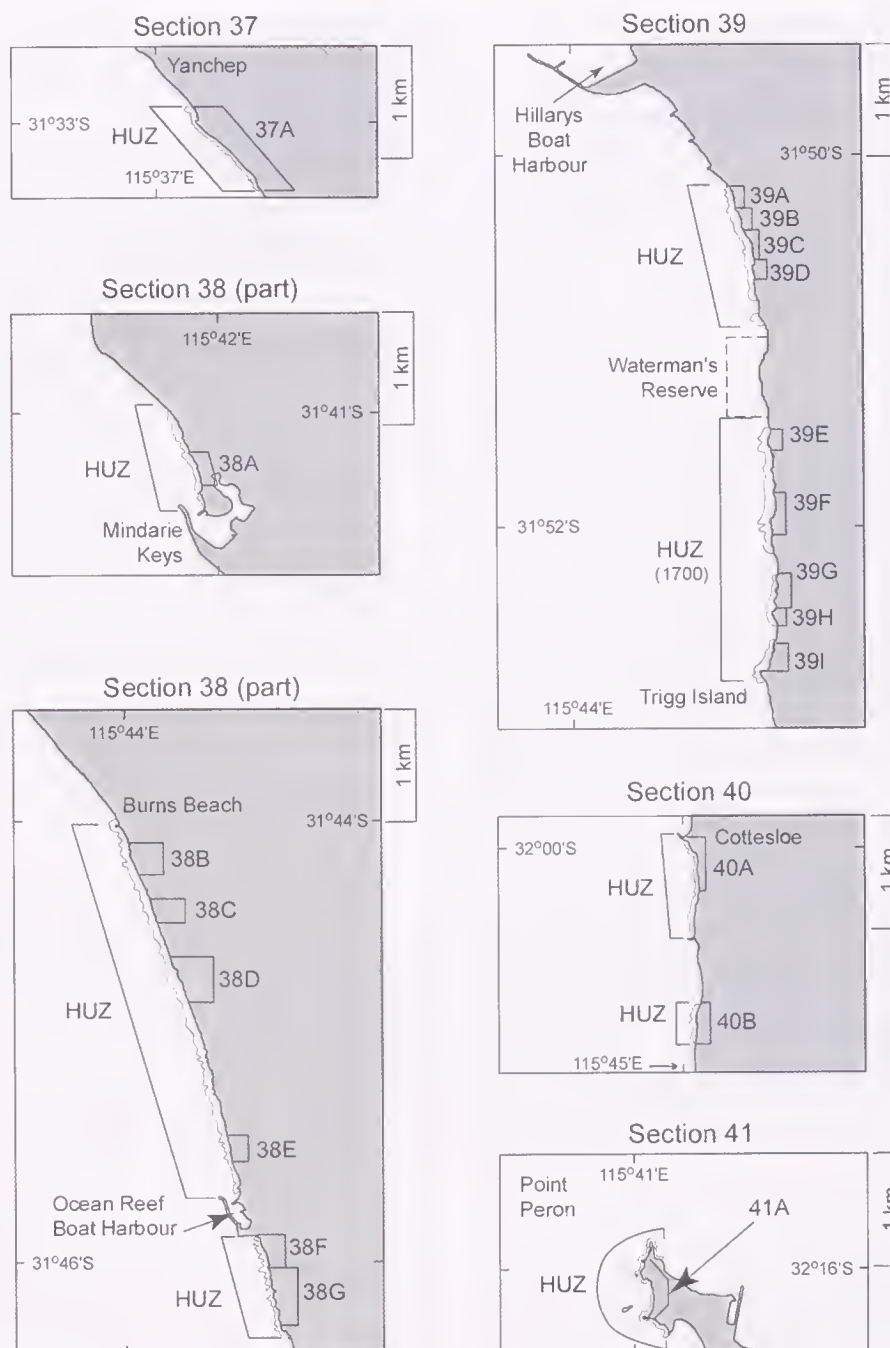

Figure 2. Maps of the high usage zones (HUZ) of each 10 nm section of the Perth abalone fishery, indicating the 20 areas where fishers were counted for estimation of effort.

by examining the relationship between the effort calculated from research and VFLO sampling and the variables that most influence effort. The variables investigated were data source (research or VFLO), year, day, count area, and fishing condition (Table 4). As a result of increasing variances in effort with increasing 710 count levels, effort and 710 count values were log transformed. Because geometric means are calculated from log transformed data the predicted values of effort will be biased. A correction for this bias was included by multiplying all back transformed estimates by $10(S^2/2)$ where S^2 is the residual mean square error for the model used to make the estimate (Baskerville 1972, Caputi et al. 1979).

The models developed from the 1997 to 1999 data were applied

to the counts of fisher participation for 2000 to 2003. During this period there were no research counts taken every 10 min from the same area. There were 120 possible count area/day combinations per year. For each combination there is either a minimum of three counts including the 710 count, a 710 count only or no count information (Table 2).

Effort for the individual count areas was summed for each 10 nm section and then extrapolated to produce an estimate of daily effort for the whole 10 nm section. The scaling factor used was the ratio of the total number of fishers in the high usage zone, to the number of fishers in the 20 count areas. This ratio was obtained from analysis of digital video taken from light aircraft at 150 m

TABLE 1.

Environmental measures included in an index of fishing conditions for the Perth recreational Roe's abalone fishery. Category values are summed across measures (columns), by choosing the corresponding value for the category from each column to give an overall index on a scale of 0 to 9. Wave height is the mean of two recordings at 7:00 and 8:00 AM, tide height is the mean of four half-hourly recordings taken from 7:00 AM, cloud cover refers to the mean of two observations at 7:00 and 8:00 AM, and rainfall refers to the period from 6:00 to 9:00 AM. Category values for the four environmental variables are summed to derive the fishing condition index.

Category Value	Wave Height (m)	Tide Height (cm)	Cloud Cover	Rainfall
0	0.00–0.30	to 30	9/8–9/8	Nil
1	0.31–0.60	31–60	7/8–9/8	Rain
2	0.61–0.90	61–90	—	—
3	0.91–1.20	>90	—	—
4	>1.20	—	—	—

(500 feet). Digital video was first successfully used on day 5 of the 2000 season. Previous attempts to use analog video footage to obtain this ratio were unsuccessful because of inadequate resolution. The ratio obtained for 2000 was applied to 1997 to 1999. A separate ratio was obtained from digital video taken on one day of each subsequent year, and used to extrapolate effort estimates for that year (Table 5).

Effort—Low Usage Zone

In the low usage zone information on effort was collected from aerial counts of fishers, with no land-based surveys. Aerial surveys were conducted on two days of each fishing season between 1997 and 2002, days 2 and 5 in 1997 and 1999 to 2002, days 1 and 4 in 1998, and on one day (day 2 only) for 2003. Counts were taken from 500 feet, beginning at Cape Bouvard in the south between 7:00 AM and 7:30 AM, and ending at Wedge Island in the north between 8:00 AM and 8:30 AM. Fishers on each reef were few enough to allow direct counts of abalone fishers. Direct aerial counts were not possible for the high usage zone because of the high density of fishers.

Aerial counts were assigned to the same 10- or 15-min time intervals used to calculate effort from the research counts, and an effort value in fisher minutes for that interval was calculated. To estimate effort for the 1.5-h period from this one count it was assumed that the distribution of fishing effort during the fishing period in these areas was the same as in the high usage zone, where research counts were taken. Thus,

$$E_L = \sum_{i=1}^n C_i T / P$$

where E_L is the effort for the low usage zone portion of a 10-nm section, n is the number of reef counts of fishers in a section, C_i is an aerial count of fishers on reef i , T is the 10 or 15 min period the count is allocated to and P is the mean proportion of the total effort for the research areas attributed to that 10 or 15-min period.

To estimate the effort for the low usage zone on days when aerial surveys were not conducted, the effort in each 10-nm section of this zone was assumed to be a constant proportion of the effort

Figure 3. Example histograms to illustrate the calculation of effort from (A) the eight counts of a research sample, and (B) three VFLO counts as a worst case example of a VFLO sample where three to five counts were made. X indicates the position of each instantaneous count of the number of fishers.

in the count areas of the high usage zone for each year, based on the two days with aerial survey information each year.

Catch Rate and Catch

Catch rates were obtained from interviews of fishers as they returned to the beach after fishing. Interviews were conducted by VFLOs, who recorded the time of the interview and the number of

abalone taken, when the fisher commenced fishing, and how long they had been fishing. Where two or more fishers were pooling their catch, the number of abalone was divided equally between fishers. Interviews were not restricted to the 20 areas with counts, but were conducted throughout the high usage zone, and from the Mandurah area, at the southern extremity of the Perth fishery. Variations in catch rates, calculated in abalone per fisher hour, were examined using ANOVA for the years 1997 to 1999. Factors examined as possible influences on catch rate were 10 nm section, year, day and fishing condition. Catch rates were skewed toward high values and were normalized using a log (catch rate + 0.05) transformation.

Multiplying the estimates of effort and mean catch rate per day provided an estimate of catch for the recreational sector, expressed as a number of abalone.

The commercial catch in the Perth fishery is monitored in whole weight only, so the mean weight of recreationally caught abalone was investigated to allow conversion of the recreational catch to whole weight for comparison with commercial catches. Weigh stations were established at an access point, the catch of fishers leaving the beach was weighed and the number of abalone per catch recorded, giving mean abalone weight per catch. During the 1999 season catch weights were recorded from 1 site per day on days 2, 4 and 6 of the fishery. During 2000 weight measurements were taken from between 3 and 7 sites per day, from a total of 10 sites, or 26 site-day combinations, including the 3 sites sampled in 1999. The relationship of mean abalone weight and

site, day and fishing condition was examined using ANOVA of data collected during the 2000 season. The relationship between mean abalone weight and site, year and fishing condition was examined using ANOVA of the data collected from the three sites sampled during the 1999 and 2000 seasons.

Commercial Sector

Commercial catch is reported for each 10 nautical mile section of the Western Australian coast from Shark Bay to the South Australian boarder. Catches in whole weight are reported on a daily basis as part of the quota management.

RESULTS

Effort—High Usage Zone

Linear regression between log effort and log 710 count, for the 187 research and VFLO samples combined, for 1997 to 1999 data, indicated a strong positive relationship ($R^2 = 0.854$, $P < 0.001$). For scenario a, where a 710 count is available, an analysis of variance with log effort as the dependent variable, was used to consider the effect of the data source (research or VFLO samples) together with log 710 count, and other variables year, day, count area and fishing condition. The data source was significant ($P = 0.028$), but accounted for only 0.2% of the sum of squares after accounting for the effect of the other variables. This is a minor influence on the model where the main effects account for 92.3% of the total sum of squares. There was no significant first order interaction between the data source and the other five explanatory variables. Therefore, the research and volunteer samples were pooled for further analysis. The main effect of year was not significant ($P = 0.554$) and there was no interaction between year and log 710 count ($P = 0.142$). Therefore, year was dropped from further analyses. Day and count area were significant as main effects ($P < 0.001$). Fishing condition proved to have important interactions and was retained. The ANOVA was repeated after removing data source and year from the model. The main effects and the most influential first order interactions are shown in Table 3. For this model the interactions of log 710 count with day, area and fishing condition account for 1.4%, 1.3% and 0.4% of the total sum of squares respectively. This model (Table 3) was used to estimate missing effort values for areas with only the 710 count. The effect of day was positive and significant, indicating that as the season progressed, and abalone were progressively fished down, the effort required for a given number of fishers to obtain the daily catch increased. The effect of fishing condition was also

positive and significant, indicating that as fishing conditions deteriorated the average individual fisher spent more time on the reef searching for their catch. This is because abalones tend to occupy the area where waves break, on the seaward section of the reef platform, and it becomes more difficult to fish as the waves become larger. This difficulty is compounded by an increase in the depth of water over the reef platform (tide height), because the majority of fishers wade without mask, snorkel or weights.

For scenario b, the ANOVA model of the five likely influences on log effort without a 710 count showed that data source was not significant as a main effect ($P = 0.051$) and accounted for only 0.3% of the total sum of squares. There were no significant first-order interactions between data source and the other explanatory variables. Therefore, research and volunteer samples were pooled. All other variables were significant as main effects ($P < 0.001$). For the remaining variables (year, day, count area and fishing condition) the dominant first-order interactions are year \times count area and fishing condition \times day (Table 4). These interactions account for 3.7% and 1.5% of the total sum of squares, respectively. This model (Table 4) was used to estimate the effort for areas with no counts for a given day. For this model effort increased as the season progressed, indicating that fishers continued to participate despite declining numbers of legal-sized abalone later in the season, and the time spent obtaining the catch increased after other factors were accounted for. The relationship with fishing condition was negative, indicating that on average as fishing conditions deteriorated there were fewer people fishing for the day, although the average fisher that did participate fished for longer to obtain their catch (scenario a).

Inclusion of year in an interaction term in the model means that it is not possible to estimate effort for a count area for any year in which there were no counts on any day during that year. For these area-year combinations, effort has been estimated using the main effects only, which still explain 87.7% of the variation. The same relationship was used to estimate the effort values for the 11 area-year combinations with no count information for 2000 to 2003.

Extrapolation of effort from the count areas per section, to the total for the high usage zone of each section, was done using the ratio of the total number of fishers, to the number within the count areas for each section. This ratio was first available from day five of the 2000 season, and was applied to the estimates for 1997 to 2000, the ratio used for extrapolation in subsequent years was available from sampling in that year (Table 5). Extrapolated estimates of effort over the total of the high usage reefs increased from 11,336 fisher-hours in 1997, to 19,216 fisher-hours in 2003 (Table 6), an increase of 70% over the 7 y.

Effort—Low Usage Zone

The mean percent of the effort from the research areas, that was attributed to each 10 or 15 min count period, ranged between 22.1% for the 710 count to 6.1% for the count at 8:20 AM (Table 7). The relationship was used to estimate the proportion of the effort for a fishing day that was described by each instantaneous count in the low usage zone. The estimates of effort indicate negligible fishing activity in sections 33, 34, 35 and 42. Between 1997 and 1999 the effort in the low usage zone decreased slightly (888–565 h), before beginning a rapid, steady rise to 1910 h in 2003. The increase in effort in the low usage zone has been most notable in sections 41 and 43 toward the southern extent of the fishery.

The total effort for the high and low usage zones combined is

dominated by section 38, which received between 43% (2000) and 55% (1998) of the total effort during the study period, averaging 49%. Section 39 received between 32% (2003) and 44% (2000), averaging 38%. Sections 38 and 39 combined accounted for between 85% (2003) and 90% (1999) averaging 87%. The high usage zone accounted for an average of 94% of the effort during the 7-year study period (Table 6) varying from 91% (2003) to 97% (1999).

Catch Rate and Catch

Analysis of variance showed that year, day, section and fishing condition were significant main effects influencing catch rate between 1997 and 1999. Because of the large sample size (4,025) many of the factors and interactions are likely to be significant. Fishing condition accounted for 10.1% and day accounted for 3.1% of the total sum of squares. Section and year each accounted for less than 1% of the total sum of squares. When the most influential interaction terms are added to the model the fit to the data is slightly improved ($R^2 = 0.190$), with fishing condition \times day accounting for 2.9% of the total sum of squares ($P < 0.001$), and day \times section 1.4% of the total sum of squares ($P < 0.001$). Given the minor influence of 10 nm section on the catch rate, and the large number of interviews, the respective daily mean catch rate was considered appropriate for estimating catch in number of abalone, on a daily basis, from the estimates of effort. The average catch rates varied between 16 and 32 abalone per hour for the days fished in 1997 to 2003.

A summary of the weight data collected between 1999 and 2003 is provided in Table 8. ANOVA results for the three sites sampled in 1999 and 2000 showed that fishing condition did not have a significant effect on mean weight. Site and year were both significant as main effects with no significant interaction between the two. The model of site and year as main effects explains 28.8% of the observed variation with 5.1% being because of site and 23.8% because of year.

Results for ANOVA of the 2000 weight data indicate that fishing condition is only significant in its interaction with site ($P = 0.034$) when modeling mean abalone weight against site, fishing condition and the interaction of site \times fishing condition. In this case fishing condition accounts for only 1.2% of the total variation explained (26.7%) and is not considered important. When the model of day, site and day \times site is considered all terms are significant. The model explains 29.0% of the observed variation with 2.7% explained by the interaction of site and day, 2.7% explained by day alone and 23.6% explained by site. Examination of the mean abalone weight from all sites measured per day indicates the site \times day interaction is most strongly influenced by an unusually low mean weight from Cottesloe on day 6, a mean from a relatively small sample (9 catches), which, together with the small percentage of error explained, suggest that the interaction is not of great importance and that the mean weight of abalone is predominantly influenced by site.

To account for the few sites sampled in 1999, the ratio of the 2000 value for the 3 sites that were measured in both years, over the value for all sites measured in 2000, has been used to derive the value that would have been expected if all sites were measured during the 1999 season. These seasonal means have been used to convert catch in number of abalone to catch in kilograms whole weight for 1999 to 2003 (Table 9). As no mean weight information is available for 1997 and 1998 the average of 1999 and 2000

TABLE 6.

Estimates of effort (fisher hours) for the low (LUZ) and high (HUZ) usage zone portion of each 10-nm section of the Perth recreational abalone fishery. Effort is from the aerial survey counts on the days indicated. LUZ % is the mean of the aerial survey effort expressed as a percent of the total effort for the HUZ count areas for that day. LUZ effort is the sum of the two effort values derived from aerial surveys and the effort for the remaining 4 days estimated as a proportion (mean %) of the total effort for the HUZ count areas per day. HUZ is the total extrapolated HUZ effort per section, and Total is the sum of the LUZ and HUZ effort.

(104.6 g) has been assumed for the conversion of the recreational catch in number of abalone to whole weight for 1997 and 1998.

The low usage zone of the Perth recreational abalone fishery represents a minor portion of the total recreational catch (Table 9), averaging only 6.3%, of the total number of abalone taken from 1997 to 2003. Total recreational catches estimated in number of

abalone increased from 1997 to 2003 with a minor decrease in 2000 because of a decrease in the estimated catch from section 38 of over 50,000 abalone. The recreational catch is taken primarily from two sections, 38 and 39, which averaged 87.2% of the catch over the 7 years (85.0% to 89.5%). Catches from both sections 38 and 39 showed an upward trend over the 7-year period, with section 38 averaging 49.3% and section 39 averaging 37.9% of the

total recreational catch from the Perth fishery measured as the number of abalone taken.

The effect of the variation in mean abalone weight, on the catch estimates in whole weight, is to accentuate increases in catch between 1997 and 1999 and to accentuate decreases between 1999 and 2000 (Table 9). The total recreational catch estimate increased by 36.0% between 1997 and 1999, then decreased by 34.5% between 1999 and 2000. This was driven by an increase in catch of 39.1% for section 38 and 48.0% for section 39 between 1997 and 1999, and a subsequent decrease in catch of 45.0% for section 38 and 23.8% for section 39 between 1999 and 2000. The total recreational catch increased by 51.9% between 1997 and 2003.

The telephone survey that began in 1999 (Hancock et al. 2003) provides an independent estimate of the recreational Roe's abalone catches from the Perth fishery as a whole. These estimates compare favorably with the results of the present field survey, with field survey results falling within the 95% confidence intervals of the telephone survey estimates (Fig. 4). The independent estimates corroborate the increasing trend in the recreational catch of Roe's abalone from the Perth fishery.

Combined Commercial and Recreational Catch

The commercial sector has caught its quota from the Perth fishery in recent years, the majority of the catch (97% to 99%) coming from the 10 nm sections 38, 39 and 41 during this study (Table 9). Catches from sections 38, 39 and 41 averaged 40%, 20% and 38% of the total commercial catch from the Perth fishery over the seven years. Nearly all of the commercial catch from section 41 comes from the low usage portion, an area of very low recreational catch.

The commercial catches are atypical for 1998 because of a one-off reduction of the commercial quota to 24 t for the 6-month period from October 1998 to March 1999 inclusive. The commercial catch from section 38 increased during 2001 to 2003, whereas the catch from section 39 decreased during 2000 to 2003, with any difference being made up from section 41.

The commercial and recreational catches are not comparable for 1998 because of the shortened commercial season. Combined commercial and recreational catches have increased 25% between

1997 and 2003, going from 69.5 to 86.6 t respectively (Table 9). The recreational catch from the Perth fishery has increased from 47.9% to 58.4% of the combined recreational and commercial catch between 1997 and 2003, although the proportion has varied during that period. Section 38 is the most productive of the overall fishery, producing an average of 45% of the annual catch, with section 39 producing an average of 29% and section 41 producing an average of 18%.

DISCUSSION

The cost of survey personnel has commonly been a major limitation on the design of creel surveys to estimate catch and effort in recreational fisheries (e.g., Jones et al. 1990, Newman et al. 1997). In this survey the use of numerous volunteers has largely overcome this limitation. The use of volunteers introduces other limitations, the primary one being a reduced ability to prescribe the areas surveyed on a daily basis. This limitation has been addressed largely by the use of predictive GLM models to estimate the missing effort values. The use of these estimation techniques was made practical by the highly predictable patterns of recreational fishing effort within the high usage zone areas counted, with the 710 count proving to be an effective indicator of effort ($R^2 = 0.951$, Table 3). The estimation of effort in areas for which no counts were available was also achieved with a high degree of confidence, with R^2 values of 0.929 and 0.877 for the two models used to estimate missing effort values (Table 4).

Creel surveys have been conducted previously using roving or access point methods, requiring stratification of the fishery by time and space (Malvestuto & Knight 1991). The structure of the Perth abalone fishery makes it possible to sample the entire fishing area of the low usage zone for one third of the fishing days, requiring the assumption that the percent of effort observed during this period in the low usage zone is representative of the remaining 4 of the 6 fishing days. It is possible to obtain measures of effort from the whole fishing period for the high usage zone, leaving space as the dimension requiring stratification. This study uses direct observation of effort from 60% of the high usage zone. Extrapolating effort from count areas to total high usage zone per section, using the ratio of the total number of fishers in the high usage zone, to the number within the combined count areas from only 1 day assumes that the ratio for that day is representative of all fishing days considered. This assumption deserves further examination in the future.

The method of estimating effort also assumes that all individuals on the reef were participating in the abalone fishery. Effort may be over estimated if there were a significant number of people that were present on the reef that were not intending to collect abalone, and subsequently not interviewed later. Evidence that this was not the case is that very few people refused an interview, and that on each day there were interviews of people that had caught zero abalone. Because Roe's abalone tend to occupy the surf zone, it is unlikely that large numbers of people would venture into this environment without reason. The occasional angler present on the reef was easily identified, and not included in the count of abalone fishers.

An advantage of this method of catch estimation, over telephone or mail surveys, is that the estimate takes into account catches by unlicensed fishers on the reef, or by fishers who have returned to fish a second quota for the day. This component of illegal fishing is captured by the direct observation of effort. Much

Figure 4. Comparison of recreational catch estimates in number of abalone from the field surveys and the telephone surveys ($\pm 95\%$ confidence intervals) for the Perth recreational Roe's abalone fishery. Phone survey data provided by T. Baharthah and N. Summer (unpublished data).

of the illegal take of more than the prescribed bag limit is also accounted for by using direct observations of catches. Other illegal activity such as out of season poaching remains unaccounted for in this study.

The low usage zone contributed between 3.5% and 9.0% of the recreational effort, and aerial surveys provide a cost effective technique for estimating this proportion. For the low usage zone, conversion of instantaneous counts to effort assumes that the distribution of fishing effort throughout the fishing period in this zone is similar to the average distribution of effort in the research areas counted in the high usage zone. Fishing is allowed throughout the fishing day in areas more than 800 m offshore. Although the amount of fishing that is conducted outside the core fishing time in offshore areas of the low usage zone is known to be low, this provides scope for an underestimation of effort. Areas affected are the low usage reefs of section 40, 42 and section 41 for 1997 only. The offshore areas of section 41 were brought under the mainland regulations in 1998. This change did not produce any discernible impact on the estimates of effort for this area, so any effects on estimates of total effort are likely to be minor.

Within the recreational sector the fishing competence and the confidence of individuals in the water vary considerably. This is reflected in the range of individual catch rates on any day, with some fishers returning to the beach with few abalone for all but the best fishing conditions and some fishers taking their bag limit of 20 abalone in as little as 5 min. It is therefore necessary to calculate mean catch rates from a large number of interviews. For this study catch rates have been calculated from between 98 and 414 interviews per day. Catch rates for the Perth recreational Roe's abalone fishery are high compared with other abalone fisheries (e.g., Lyle & Smith 1998, Worthington et al. 1998), and fishing times are low, reflecting the high densities of this species.

The recreational catches have been converted to estimates of whole weight for comparison with commercial catches. The consistent and highly significant change in the mean weight of abalone taken in the recreational fishery between 1999 and 2000 highlights the possibility that assuming a mean weight for the 1997 and 1998 seasons, on the basis of measurements made in 1999 and 2000, may introduce an appreciable bias in the estimation of catch weight for these years. Trends in catch indicated by number of abalone taken would be more reliable for these years, and comparisons with the commercial catch for 1997 and 1998 should be interpreted with added caution. The mean weights for 2000 to 2003, which have been sampled from at least 9 sites have been relatively consistent varying from 90 to 96 g. The high mean weight in 1999 may have been affected by the low level of sampling in the first year when mean weights were sampled.

The recreational catch from the high usage zone is highly dominated by sections 38 and 39, and there was a substantial decrease in fishing effort in 2000 (Table 6), particularly evident in section 38. Reasons for this decrease in effort are likely to include fishing conditions that were more challenging.

The nature of recreational catch estimates means that they are generally based on a set of assumptions that are difficult to test. This led Pollock et al. (1994) to conclude that the only real test of the accuracy of these estimates is corroboration from two or more independent estimates. Given the time and cost involved in estimating recreational catches, the availability of two independent estimates is unusual. The telephone survey was used to estimate recreational abalone participation rates, fishing effort and catch for the three exploited species of abalone in Western Australia. A

stratified random sample comprising about 800 of the up to 21,000 abalone license holders were contacted by phone (Hancock et al. 2003). The close agreement between the two independent estimates of the recreational Roe's abalone catch (Fig. 4) greatly increases the confidence that each represents a valid estimate of the catch for this fishery.

In no other abalone fishery in the world is there such a focus of fishing activity adjoining the suburban area of a major city. Also, most abalone species throughout the world are predominantly subtidal and occur in lower densities, meaning that fishers require a higher level of expertise and equipment to access them. The more diffuse nature of most abalone fisheries tends to favor mail or telephone surveys as a means of estimating the recreational catch and effort (Weithman 1991) where recreational fishing license information can be used to target fishers.

Abalone fisheries throughout the world are exploited to different extents by the commercial and recreational sectors, but the recreational catch, where it has been estimated, is generally an important component of the legal catch, with recreational fishing effort tending to increase (Teirney et al. 1997, Anon. 1998, 1999, Bradford 1998, Lyle & Smith 1998, Worthington et al. 1998). The combination of their high value and accessibility makes it important to monitor catch trends in these fisheries.

In the Perth fishery the Roe's abalone catch is high, reaching 42t for a 10 nm section of coast, and concentrated in just 30 nm (sections 38, 39 and 41). Of these, section 41 is nearly exclusively fished by the commercial sector. Sections 38 and 39 are the most heavily exploited, with the recreational sector taking between 54% and 72% of the catch from these sections during the 7-year period of this study. Examination of the population structure of Roe's abalone has demonstrated that individual stocks are separated by less than 13 km of coast (Hancock 2000). This scale is well represented by the patches of semicontinuous reef within each 10 nm section of the Perth fishery. The present results provide catch and effort information on a scale of the individual biological stocks within the fishery. Any stock assessment for this fishery should be conducted on the same spatial scale.

The recreational catch increased 65% during the period of the study, and now exceeds the commercial catch, whereas the commercial catch is fixed via quotas. This study provides the catch and effort information required to manage this intensively used fishery on the scale of the biological stocks that make up the fishery. This has been achieved despite the fine scale spatial subdivision of individual stocks.

ACKNOWLEDGMENTS

The authors thank T. Baharthah and N. Sumner for permission to quote results of their telephone survey. This project was supported by funding from the West Coast Abalone Divers Association through the Department of Fisheries WA, the recreational fishing sector through the Recreational Fishing Advisory Committee and from the Commercial and Recreational fishing programs of the Department of Fisheries WA. This work was completed as part of the PhD thesis of B. Hancock, who thanks Drs. M. S. Johnson, R. Black and L. Joll who supervised this thesis. Field assistance was provided by numerous staff of Fisheries WA and volunteers, particularly the Volunteer Fisheries Liaison Officers, without whose help the surveys would not have been possible.

TRANSPORT AND RECRUITMENT OF SILVER-LIP PEARL OYSTER LARVAE ON AUSTRALIA'S NORTH WEST SHELF

ABSTRACT Silver-lip pearl oyster (*Pinctada maxima*) spat surveyed in the Eighty Mile Beach section of the North West Shelf have been used in conjunction with outputs from a particle dispersion model to identify likely spawning grounds. The dispersion model consisted of a 3-dimensional regional circulation model in which large numbers of individual particles were tracked over the period 1994 to 1999. From the settlement areas defined by the spat data, larvae were tracked back in time over their estimated pelagic phase of 24–31 days within the main spawning period of mid October to late December. The reverse calculation was also undertaken looking at larval dispersion from known broodstock populations. Results demonstrate that large tidal currents in the region move larvae back and forth across the shelf, whereas lower frequency currents influence their net transport. Whereas some model larvae traveled more than 60 km, most were transported less than 30 km. The model results suggest that spawning in the Eighty Mile Beach region is concentrated around the recently surveyed broodstock distribution between 8 and 15 m depth, with potential smaller contributions from the northeast. These spawning events are likely to lead to successful recruitment locally and alongshore to the southwest. They also feed larvae into neighboring shallow coastal environments (through tidal oscillations) and deeper waters to the west (~20 m). However, spat abundances seem to be low in these areas, suggesting that recruitment is strongly limited by habitat availability and possibly high mortality rates in shallow water. High local abundances of broodstock and spat observed occasionally in deeper water (~30 m) seem to be supported by intermittent larval transport from inshore populations. However, spawning in this area seems to contribute little to recruitment in the inshore populations.

KEY WORDS: *Pinctada maxima*, oysters, larvae, larval transport, recruitment

INTRODUCTION

The pearling industry on Australia's North West Shelf (NWS) relies substantially on shell caught from the inshore waters of Eighty Mile Beach (Fig. 1). The most sought after species is the silver-lip pearl oyster, *Pinctada maxima* (Jameson) that produces the silver-white South Sea pearl. Oyster beds on the NWS provide "wild shell," which is collected by divers, before being seeded and placed back on the seabed in framed net enclosures or "panels." After recovering for a few months, they are transported to farms where the pearls can develop. These activities are managed as a gauntlet fishery, where oysters are caught at the optimum size for seeding (120–160 mm) leaving the larger mother-of-pearl (MOP, >175 mm) as breeding stock.

Recently surveyed MOP distributions show increasing abundance with water depth, whereas the abundance of recruits (120–160 mm) tends to decrease (Hart & Friedman 2004). This decoupling of broodstock and recruitment might be explained by net onshore transport of larvae spawned in deeper waters being offset by high rates of fishing and natural mortality in shallow waters. This is the basis for the long-standing belief within the pearling industry that deep "unfished" stocks could be broodstock source for the commercially fished inshore stock. However, prior to this study, such a hypothesis had not been tested.

It is clearly critical to the management of the fishery to understand the *P. maxima* reproductive cycle (Rose et al. 1990) and establish the geographical extent of the spawning stock supporting the fishery. The objective of this study is to use a particle dispersion model in combination with results from pearl oyster surveys to investigate larval transport and settlement. Specifically, poten-

tial settlement distributions have been estimated based on surveyed MOP spawning populations and compared with results from spat abundance surveys. The reverse calculation has also been made, estimating potential spawning distributions based on spat abundance data and comparing these with the MOP distribution data. This has allowed us to test the hypothesis that deep-water MOP stocks support inshore recruitment, and population connectivity relationships more generally, within *P. maxima* stocks.

MATERIALS AND METHODS

Larval dispersion patterns were modeled by tracking particles transported by ocean currents estimated from a circulation model for the North West Shelf. Particle trajectories were used to estimate both potential settlement sites and potential spawning sites. Spawning distributions were based on a MOP survey conducted in September 2001, whereas settlement distributions were based on 3 years (2001 to 2003) of spat surveys. These surveys were focused off Eighty Mile Beach, where most of the fishery is concentrated.

Circulation Model

The circulation model was developed as part of the North West Shelf Joint Environmental Management Study (NWSJEMS 2002, Condie et al. 2003) and was based on code referred to as MECO (Model for Estuaries and Coastal Oceans). MECO is a general-purpose finite-difference hydrodynamic model applicable to scales ranging from estuaries to ocean basins. It uses a curvilinear orthogonal grid in the horizontal and fixed "z" coordinates in the vertical. A comprehensive description of the underlying theory is provided in the MECO Scientific Manual (Herzfeld et al. 2002). MECO has found previous applications in systems such as the Port Phillip Bay (Walker 1999), Bass Strait, the Great Australian Bight

and Southeastern Australia (Bruce et al. 2001) and the Gulf of Carpentaria (Condie et al. 1999).

MECO was implemented for the NWS on a rotated latitude-longitude grid with horizontal resolution of approximately 10 km (Condie et al. 2005a). This grid extended from Cape Cuvier in the southwest to the Bonaparte Archipelago in the northeast and well beyond the shelf break (Fig. 1). The vertical resolution expanded from 3 m near the surface to a maximum of 200 m at its maximum depth of 1200 m. Truncating the depth at this level had little effect on the circulation, but significantly improved computational times. The bathymetry was prescribed by spatially averaging a 30 sec (0.9 km) product provided by Geosciences Australia onto the model grid.

Inputs required by the model included forcing caused by wind, atmospheric pressure gradients, and open boundary conditions such as temperature, salinity, and sea level. Wind fields were taken from the NCEP-NCAR 40-y reanalysis dataset (Kalnay et al. 1996). These fields had a 12 hourly time-step and a spatial resolution of 1.8° , which were linearly interpolated onto the model time-step and model grid. The interpolated product generally showed good agreement with locally measured winds at subdiurnal frequencies (Fig. 2a). However, smaller scale processes, such as the daily sea breeze and occasional tropical cyclones, were less adequately resolved. Winds during the major spawning period of mid October to December were predominantly from the west.

Temperature and salinity fields around the lateral boundaries of the model were interpolated from a global circulation model known as the Australian Community Ocean Model or ACOM (Schiller et al. 2000). In the absence of reliable surface fluxes, interior temperatures and salinities were modified by relaxing them towards ACOM values with a 10-day relaxation timescale. Sea levels on the boundaries were also taken from ACOM output, with the addition of tidal constituents derived from tide gauge observations around the Cape Cuvier and Bonaparte Archipelago areas in combination with global tidal model estimates along the offshore boundaries (Eanes & Bettadpur 1995).

Particle Dispersion and Tracking

The modeled currents provided an indication of the instantaneous movements of larvae in the water column. However, additional information was required to estimate advection and dispersion patterns. Individual-based particle-tracking techniques were adopted for this purpose. In the absence of any detailed information on larval swimming behavior, all particles were assumed to be nonmotile and neutrally buoyant. These assumptions are relatively easy to justify in the extremely energetic environment of Eighty Mile Beach, where tidal currents and turbulent mixing velocities would normally be expected to far exceed realistic larval swimming speeds (e.g., Condie 1999).

A large number ($\sim 10^5$) of neutrally buoyant particles were initially seeded randomly through the water column across the model domain, with highest concentrations on the inner shelf. The circulation and particle movement calculations were then conducted simultaneously, with particle positions being updated every 10 min by the interpolated model current velocities. A random walk component was also added to the trajectory to represent the dispersive influence of turbulent motions not resolved by the circulation model. Each particle was individually tracked and its location recorded every 3 hours.

Particles followed complex paths that were sensitive to their initial location. Individual trajectories therefore provided a limited view of likely dispersion patterns associated with large numbers of larvae. A statistical description of the dispersion results was therefore developed from large numbers of trajectories (Condie et al. 2005b). From the spawning areas defined by the MOP data, larvae were tracked over their estimated pelagic phase of 24–31 days within the main spawning period of mid October to late December (Rose et al. 1990). More specifically, particles within the spawning areas (defined later) at midnight on October 15 were tracked for 24 days, after which their locations were recorded every 3 hours over

Figure 2. (a) Comparison between local observed winds at Port Hedland and the NCEP-NCAR winds used to force the model for June 1994. (b) Comparisons of observed and modeled low-frequency sea-level difference between Broome and Port Hedland, based on a 28 day running mean.

the following 7 days. The process was then repeated starting 3 h later (i.e., 3:00 AM on October 15) and then at all subsequent 3 hourly steps until the end of the 31-day pelagic phase corresponded to December 31. To ensure that the results were not unduly dominated by those particles remaining within spawning areas for extended periods, each particle was only permitted to initiate a new trajectory 7 days after it had initiated the last one.

The combination of all recorded locations provided the final estimate of potential settlement distribution. This differs from an estimate of actual settlement, which would require additional factors such as habitat distribution, habitat preference, and larval mortality to be taken into account. The approach taken to estimate spawning areas defined by the spat data was the same as that described above, except that trajectories were tracked back in time. Results were obtained for all modeled years (1994 to 1999), which were further amalgamated into an average distribution over the entire 5-year modeling period.

Biological Surveys

A pearl oyster stock survey conducted in September 2001 revealed that distributions are largely limited by habitat availability (Hart & Friedman 2004). This finding, combined with the longevity of the large broodstock (or MOP) (Rose et al. 1990), suggests that distributions are likely to be relatively stable and hence that the 2001 MOP distributions represented an acceptable proxy for the modeling period (1994–1999). A measure of the relative abundance of MOP was based on the average number of shell collected for each hour the vessel drifted within the target populations (Hart & Friedman 2004).

Spat surveys (measuring 0+ and 1+ age classes) were undertaken over the 3-year period from 2001 to 2003 using the method described in (Hart & Joll 2005). Because only partial coverage was provided by each survey, the three were combined here into a single estimate of settlement distribution. In brief, the spat methodology involved examining adult shell collected by commercial divers, and counting any attached spat (Hart & Joll 2005). These counts were assumed to be representative of relative spat densities across all suitable habitats available in the area. The average number of spat per shell within a 10-m grid cell therefore provided a measure of spat relative abundance. Information on the spat year classes were not required for the current analysis, however were useful for evaluating year-to-year trends in settlement.

RESULTS

Modeled Currents and Sea Levels

Instantaneous current patterns on the NWS were dominated by strong tides, with speeds approaching 2 m s^{-1} during the spring tide (Fig. 3a). In the main fishing areas around Eighty Mile Beach, the tidal movements were predominantly in the cross-shore direction and diminished with distance offshore. The model currents have been shown to compare favorably with observations around the Dampier region to the west (Condie et al. 2005a). However, no direct current observations have been taken in the Eighty Mile Beach region (Godfrey & Mansbridge 2000). The best indication of model performance in the local region was therefore provided through comparisons of sea level variability.

Sea level was strongly dominated by the very large tidal signal, with ranges up to 10 m in King Sound. The model generally

reproduced the tidal sea-level signal quite accurately, with correlation coefficients increasing from $r = 0.87$ at Broome to $r = 0.96$ at Port Hedland (Condie et al. 2005a). However, it is the lower frequency component that largely controls net transport over the pelagic larval phase (24–31 days). Because subtidal currents are generally highly correlated with subtidal sea-level differences, model performance in the Eighty Mile Beach region was examined in terms of sea-level differences between Broome and Port Hedland. This analysis revealed a strong coastally trapped wave signal in the model and observations, with a period of approximately 14 days in both instances. However, it is the variability over the typical larval phase that is of most immediate interest. For example, comparisons of the running mean of the sea-level difference over 28 days produced a correlation of $r = 0.89$ (Fig. 2b).

Monthly averaged surface currents during the period October to December (main spawning period) were typically northeastward at a few centimeters per second (Fig. 3b). However, close to Eighty Mile Beach the surface flow was directed offshore, suggesting a net upwelling over the monthly timescale. These currents patterns were a response to the prevailing westerly winds and are consistent with the few satellite tracked ocean drifters observed in the area at this time of the year (Cresswell et al. 1993). The depth-averaged currents were weaker and tended to form a clockwise gyre off Eighty Mile Beach (Fig. 3c). The resulting flow close to the coast was predominantly westward, counter to the prevailing winds. This monthly averaged pattern persisted throughout the spawning period (Fig. 3d).

Estimates of Settlement Distribution

The surveyed MOP distribution (Fig. 4a) showed low to moderate relative abundances ($0\text{--}60 \text{ h}^{-1}$) around the 10 m depth contour, with a tendency towards higher values at the northern extremity of the sampling area ($60\text{--}120 \text{ h}^{-1}$). However, the largest abundances ($110\text{--}160 \text{ h}^{-1}$) were found in a patch further offshore around the 30-m depth contour. Potential larval settlement distributions were estimated by assuming that MOP survey abundances were proportional to the spawning population (although results were qualitatively similar when all cells with surveyed MOP were given equal weighting).

Results averaged across the model runs (1994 to 1999) indicated two main potential settlement areas (Fig. 4b). The larger was centered just inshore of the 10 m depth contour ($121^{\circ}24'\text{E}$, $19^{\circ}6'\text{S}$), with the smaller centered just inshore of the 20 m depth contour ($121^{\circ}7'\text{E}$, $19^{\circ}11'\text{S}$). Because larvae could potentially settle at any time during the tidal cycle, the size of these areas was largely determined by the dimensions of the tidal ellipse. The relative settlement rate in the two areas varied from year to year and in 1994 the model results showed more settlement offshore than onshore (not shown). However, the predicted settlement areas were not associated with the two distinct spawning areas. Rather, most MOP regions contributed to both settlement areas (C to F in Fig. 4a and Fig. 5a) reflecting temporal and spatial variability in flow patterns within the 2.5-month spawning period. The main exception to these trends was the surveyed area near the 30 m depth contour, whose modeled larvae tended to move into deeper water ($\geq 40 \text{ m}$) to the southwest without contributing to either of the main settlement areas (A in Fig. 4a and Fig. 5a).

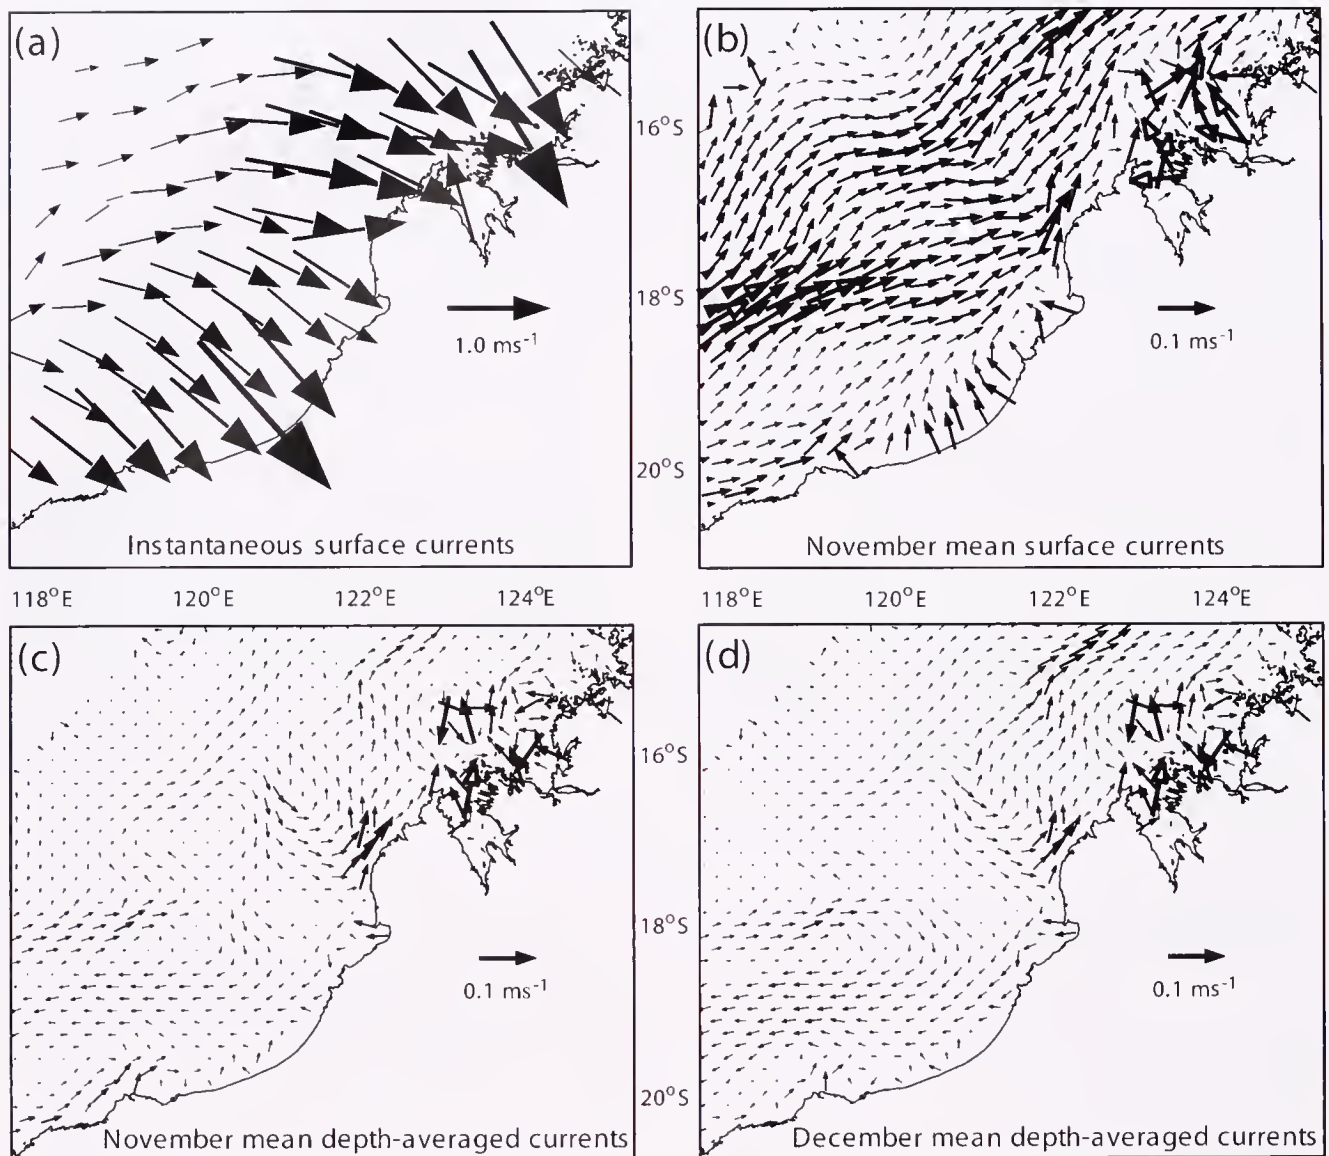

Figure 3. (a) Example of flood-tide currents under spring-tide conditions. (b) Monthly mean surface currents (depth = 1.5 m) for November based on 6 years of model runs (1994–1999). (c) Monthly mean depth-averaged currents for November based on 6 years of model runs (1994–1999). (d) AS in (c) for December.

The model predicted settlement region covers nearly all the areas surveyed for spat, with predicted high settling rates corresponding with the main survey area (cf. Fig. 4b and 4c). However, spat surveyed further offshore and to the north (Fig. 4c) corresponded to low settlement rates and may have originated from MOP outside the MOP survey area. There were also large areas of predicted settlement, both near-shore and offshore, that were not in the area of the spat surveys. Whereas spat may have existed in some of these areas, the limited availability of suitable habitat would likely have resulted in low abundances.

Estimates of Spawning Distribution

The surveyed spat distribution, as described by Hart and Joll (2005), tended to follow the 10-m depth contour along Eighty Mile Beach at low to medium relative abundances (0–20 per thousand shells) with a bias towards deeper water to the north (Fig. 4c). There were a few high abundance of cells (20–30 per thousand

shells) in this zone, with more in habitats further offshore around the 15-m and 30-m depth contours (Fig. 4c). Potential spawning distributions were estimated by assuming that the spat survey abundances were proportional to the settling population (although results were qualitatively very similar when all cells with surveyed spat were given equal weighting).

Estimated spawning areas associated with the surveyed spat distributions were centered just inshore of the 10-m depth contour ($121^{\circ}24'E$, $19^{\circ}6'S$), but relatively high values extended offshore almost to the 20-m depth contour and onshore almost to the coast (Fig. 4d). The size of these areas was again a function of the tidal ellipse and there was very limited interannual variability (not shown). Spat counted in the main survey area along the 10-m depth contour were mainly spawned in this area (C, D and E in Fig. 4c and 5b), although cell E also received model larvae from further to the northeast. The model indicated that spat surveyed further south (B) and north (F) would have come from spawning in deeper water, whereas those offshore around the 30-m depth contour (A)

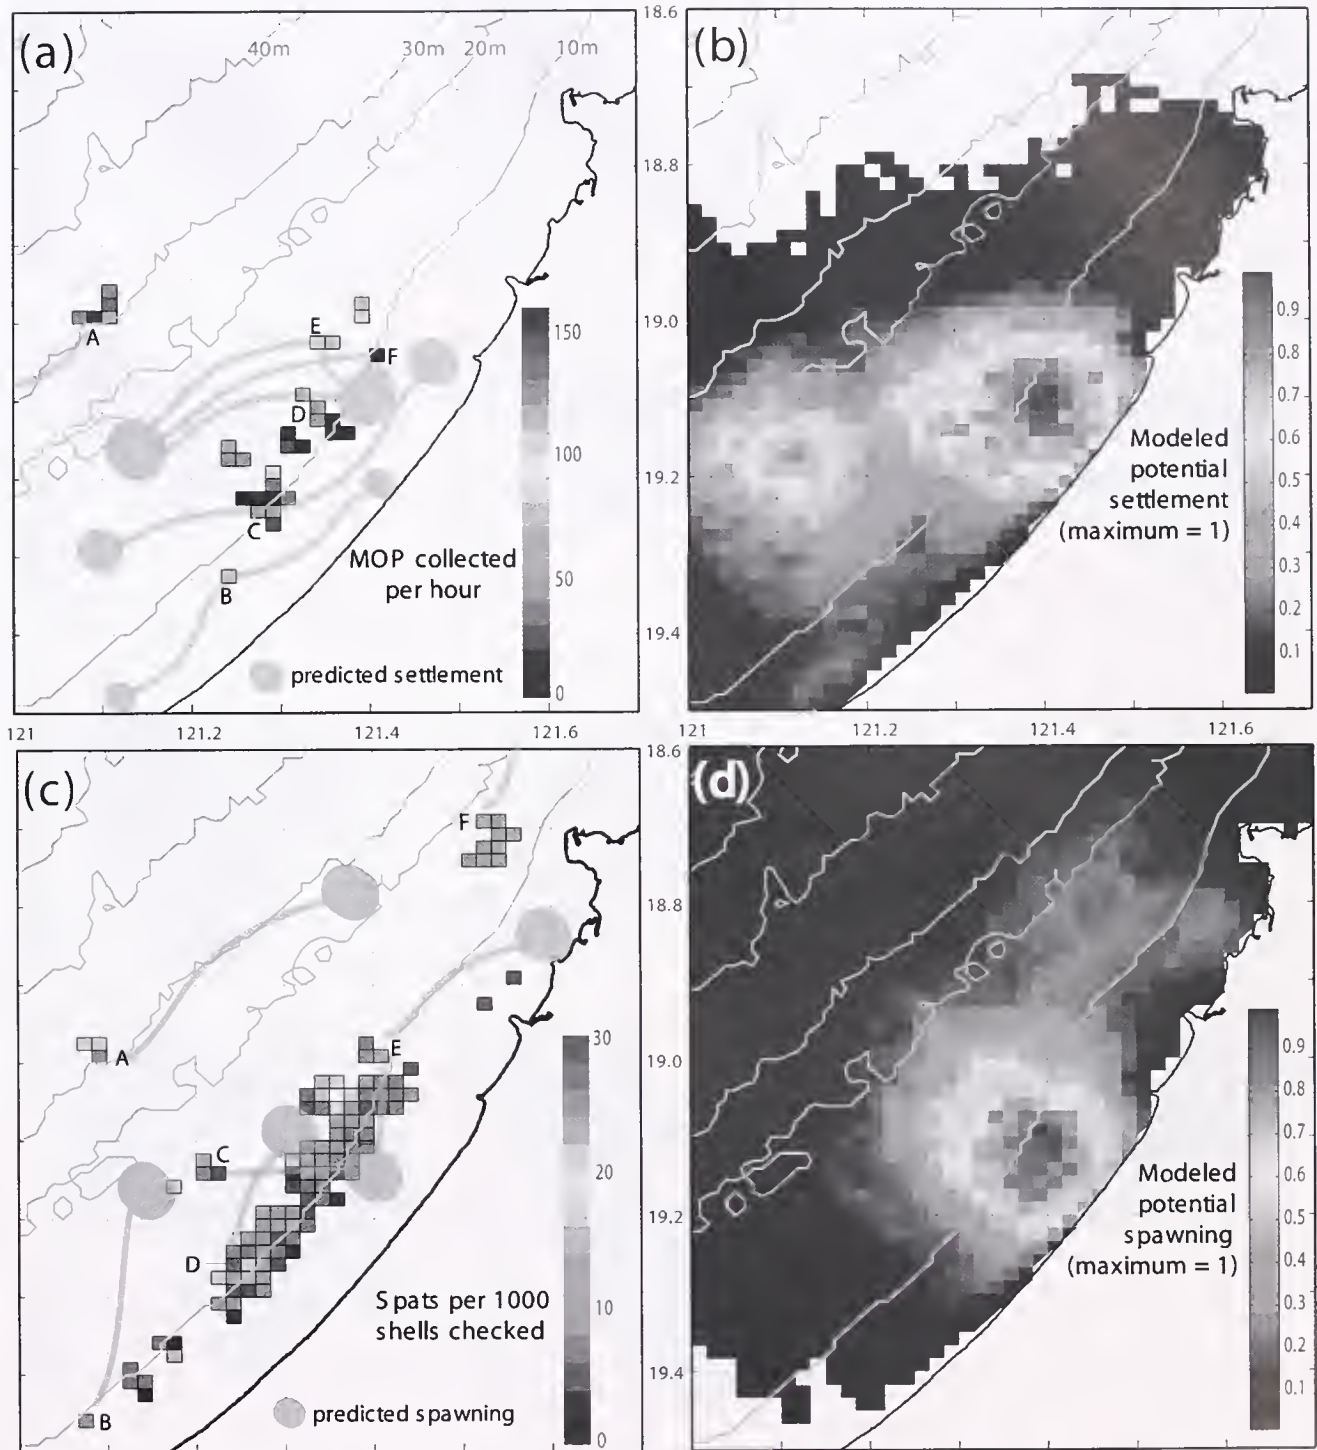

Figure 4. (a) Relative abundance of MOP off Eighty Mile Beach expressed in terms of the number collected per hour of vessel drift during the survey (Hart & Friedman 2004) overlain by a schematic summary of modeled downstream settlement areas from selected cells A to F (corresponding quantitative predictions for A to F are shown in Fig. 5a). (b) Estimated settlement distribution (ignoring habitat availability) averaged across all model years (arbitrary units with maximum = 1). (c) Relative abundance of spat off Eighty Mile Beach expressed in terms of average number of spats found per 1,000 shells checked (Hart & Joll 2005) overlain by a schematic summary of modeled upstream spawning areas from selected cells A to F (corresponding quantitative predictions for A to F are shown in Fig. 5b). (d) Estimated spawning distribution averaged across all model years (arbitrary units with maximum = 1).

would have come from marginally shallower depths to the north-east (Fig. 4c and 5b).

Apart from extending into very shallow water, the spawning area estimated from the surveyed spat (Fig. 4d) was con-

sistent with the surveyed MOP distribution (Fig. 4a). The main exception was the offshore MOP (A in Fig. 4a), which the model suggests spawn into deeper water outside of the spat survey region (Fig. 5a).

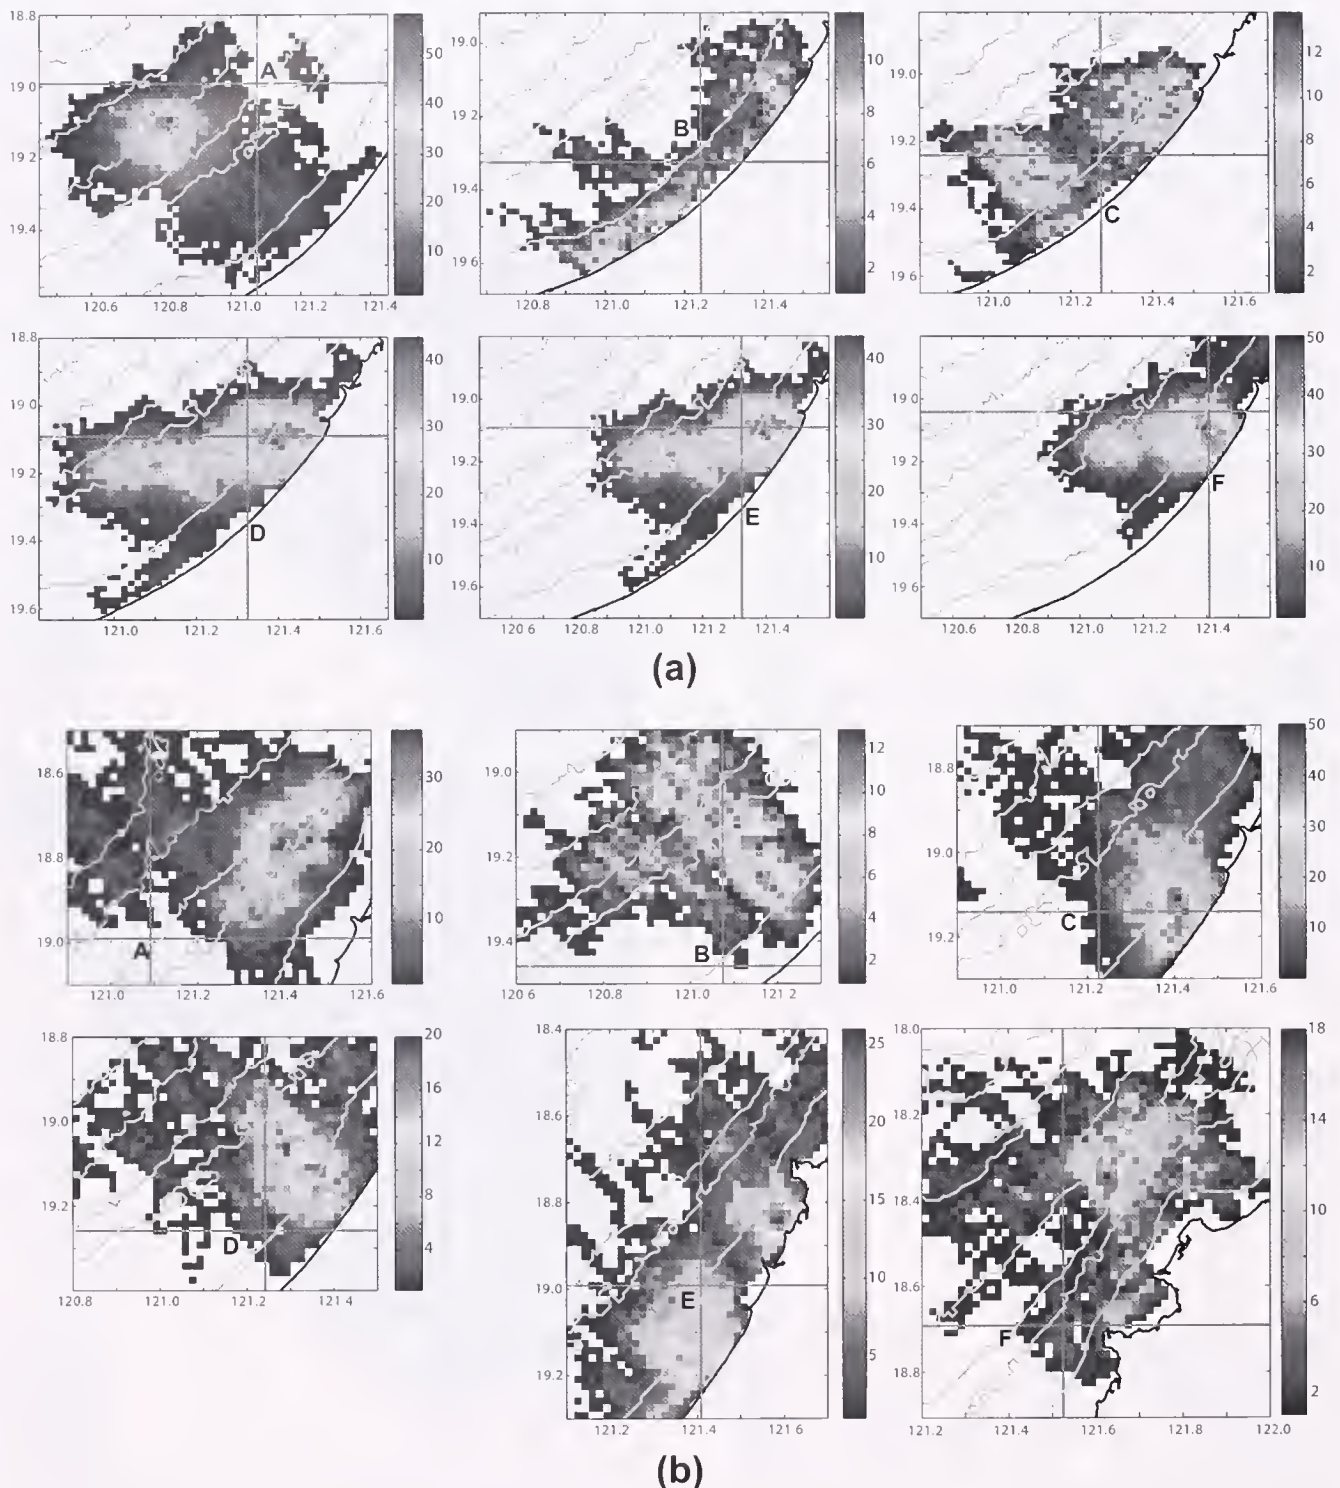

Figure 5. (a) Relative likelihood of settlement after spawning at the cell marked by the cross-hairs. (b) Relative likelihood of spawning contributing to settlement at the cell marked by the cross-hairs. In both (a) and (b) results are averaged across all model years (1994–1999), the color-bars indicate the number of trajectories connecting a given cell with the cell marked by the cross-hairs, and depth contours are at 10-m intervals.

DISCUSSION

The overall picture emerging from the model results is that spawning in the Eighty Mile Beach region is concentrated around the surveyed MOP distribution between 8- and 15-m depth, with

potential smaller contributions from further northeast. These spawning events are likely to lead to successful recruitment locally and alongshore to the southwest so that the main pearl oyster producing populations are likely to be self seeding. These spawning events also feed larvae into neighboring shallow coastal envi-

ronments (through tidal oscillations) and deeper waters to the west (~20 m). However, spat abundances appear to be lower in these areas, suggesting that recruitment is either limited by habitat availability and possibly increased mortality in shallow water, or else spat larvae preferentially select other settlement habitats (as opposed to live adult shell). High local abundances of MOP and spat observed in deeper water (~30 m) appear to be supported by intermittent larval transport from inshore populations and may be further assisted by high quality habitat and low mortality rates. However, spawning in this area seems to contribute little to recruitment in the inshore populations.

The validity of the settlement and spawning estimates is dependent on a number of factors. The first is the accuracy of the predicted circulation. Whereas the model has been shown to perform relatively well in the Dampier region (Condie et al. 2005a), the data available for validation near the fishing grounds was limited to sea-level information. The second factor is the comprehensiveness of the MOP and spat surveys. For example, some habitats may have been under sampled and others may still be undiscovered.

A third source of model uncertainty is associated with larval behavior. For example, larvae remaining close to the surface would tend to follow the wind dominated circulation to the north-east (Fig. 3b), rather than the depth averaged circulation (Fig. 3c). This seems unlikely in this region given that tidal motions drive energetic vertical mixing out to at least the 30-m depth contour and that the MOP and spat surveys suggest transport to the southwest. A potentially more significant behavioral characteristic would be

any ability of larvae to select settlement sites. During the week long period in which settlement can occur (Rose et al. 1990), tidal motions carry individual larvae back and forward up to 20 km in the cross-shore direction. If larvae encountered preferred habitats over depths from around 8–15 m deep during this period, then the estimated settlement distribution based on the observed MOP (Fig. 4b) would be very similar to the observed spat distribution (Fig. 4c).

The results of the model suggest that the long-standing hypothesis within the pearling industry, namely that deeper “unfished” stocks are a broodstock source for the commercially fished inshore stock, is not likely to be true. The inshore stocks appear to be self-sustaining, and may even be providing larvae to deeper stocks in irregular recruitment events. These findings have important management implications, particularly if fishing for MOP were to recommence at some time in the future. However, current management and fishing strategies seem to protect the critical broodstock that support the long-term sustainability of the existing “gauntlet” fishery.

ACKNOWLEDGMENTS

The authors thank the Pearling industry, particularly Paspaley Pearls and Broome Pearls Pty Ltd for allowing the use of their vessels and pearl divers to conduct the spat sampling and research surveys. This work was supported by grants from the Pearling Industry of Western Australia, the Western Australian Fisheries Department and the Fisheries Research and Development Corporation (FRDC).

EFFECTS OF SEASON, TEMPERATURE CONTROL, BROODSTOCK CONDITIONING PERIOD AND HANDLING ON INCIDENCE OF CONTROLLED AND UNCONTROLLED SPAWNING OF GREENLIP ABALONE (*HALIOTIS LAEVIGATA* DONOVAN) IN WESTERN AUSTRALIA

KYLIE FREEMAN,^{1*} SABINE DAUME,¹ MATTHEW ROWE,^{1,2} STEVE PARSONS,² RIC LAMBERT² AND GREG B. MAGUIRE¹

ABSTRACT Managing the broodstock conditioning process is important to the successful establishment of an abalone industry that can reliably produce juveniles from captive stock and pursue selective breeding. Four conditioning periods of 6, 8, 10 and 12 wk intervals were tested with captive greenlip abalone (*Haliotis laevigata*), using a constant conditioning temperature and ambient temperature as a control. The conditioning periods of 6, 8, 10 and 12 wks are equivalent to ~420, 560, 700 and 840 EAT (effective accumulative temperature), based on a biological zero point (BZP) of 6.9°C for gonad development. Greenlip abalone broodstock collected from the wild (87.5–142.1 mm in shell length and 108.2–482.8 g in whole weight) were spawned in all seasons including numerous induced spawnings outside of the normal breeding period with conditioned stock. Over the whole trial period, greater egg production from prescheduled spawnings occurred in the conditioned group with an average of 1.70×10^6 eggs per tub of 5 female abalone per planned spawning, compared with abalone held in ambient control tubs that only produced an average of 0.40×10^6 eggs per tub. Animals that were spawned every 8 wks produced the largest average number of eggs per holding tub, however, there was very little difference between conditioning periods in terms of number of successful spawnings per spawning round. The egg production for all planned spawnings was highest before the “natural spawning season” for greenlip abalone. In comparison, the highest numbers of unplanned spawnings occurred around the natural spawning period for the conditioned and control groups. Handling abalone did reduce egg production within the trial, but this was not statistically significant. Histological examination showed that using the visual gonad index is not a good indication of maturation of the abalone and confirmed that abalone can be conditioned out of season.

KEY WORDS: *Haliotis laevigata*, broodstock conditioning, abalone, handling, conditioning periods, gonad histology.

INTRODUCTION

Aquaculture of abalone is practiced in many countries worldwide and in Australia is an emerging industry across the southern mainland states and Tasmania (Fleming 2000). However, little research has been carried out in Australia on conditioning of mature abalone for use as broodstock. Understanding the broodstock conditioning process is important to the successful establishment of this industry by ensuring reliable and cost effective production of juveniles and for selective breeding (Li 2001). The ability to have ripe individuals year-around or at predictable times in the year allows the culturist to schedule the hatchery process to occur at the most favorable time of the year for growth and survival (Hahn 1989). The use of conditioned abalone overcomes problems relating to the use of wild-caught adult abalone for broodstock including access to stock (through state regulations), variability in the condition of stock and the reliability of successful spawnings (Fleming 2001).

The major species being farmed in Western Australia is the greenlip abalone *Haliotis laevigata* Donovan. This species is distributed along the southern coastline from western Victoria to Cape Naturaliste in Western Australia and around islands near Tasmania (Freeman 2001). Broodstock conditioning research has been conducted on this species in that state (Daume & Ryan 2004) and on the genetically distinct population (Elliot et al. 2001) in Tasmania, where ambient temperatures are much lower than in Western Australia and exhibit greater seasonal variation (Leonart 1992, Grubert & Ritar 2002, 2003, Freeman 2001). One of the major problems in investigating abalone reproduction is the short period of natural spawning (Hahn 1989). The natural spawning

season for greenlip abalone on the south coast of Western Australia is from late September/early October through to December (Wells & Mulvey 1992).

Several biological processes are involved when conditioning abalone, for example, gametogenesis for females and males, synthesis of hormones controlling gametogenesis and spawning, and for the female only, vitellogenesis and synthesis of hormones controlling vitellogenesis. In addition to the gonad being ripe, the animal must be in the proper physiological state and in appropriate environmental conditions to promote spawning (Hahn 1989). Many factors have been found to influence conditioning in different species of abalone including water temperature, food, photoperiod or a combination of these variables (Hahn 1989). Uki and Kikuchi (1982) considered nutrition as an important factor for gonad development in abalone and Webber (1970) found that water temperature controls the reproductive cycle for many marine gastropods. In most species of abalone, temperature strongly influences rates of gonad development; its effect is cumulative above a certain threshold temperature and is known to vary between species (Grubert & Ritar 2003). The threshold temperature, better referred to as the “biological zero point” (BZP) was first identified by Kikuchi and Uki (1974). They determined the effective accumulative temperature in degree-days (EAT°C-days) for gonad conditioning of *Haliotis discus hamai* Ito and *Haliotis discus* Reeve by subtracting the BZP from the daily water temperature and adding this figure over the conditioning period (in days). *H. discus hamai* was found to have a BZP of 7.6°C (Uki & Kikuchi 1984). Grubert and Ritar (2003) studied the effect of temperature and conditioning interval on the spawning success of wild-caught blacklip (*Haliotis rubra* Leach) and greenlip abalone fed an artificial diet. They found that unlike *H. rubra*, male and female *H. laevigata* have a higher spawning rate and gamete production when conditioned at 16°C compared with 18°C. In a preceding

*Corresponding author. E-mail: kfreeman@fish.wa.gov.au

experiment, Grubert and Ritar (2002) estimated BZP values for gonadal and larval development for *H. rubra* as 7.8°C and 7.9°C respectively and for *H. laevigata* 6.9°C and 7.2°C respectively. In Leonart's (1992) research into broodstock conditioning of green-lip abalone, the mean temperature during conditioning was 16°C and the number of elapsed degree-days was recorded as 1,750, which when corrected using a BZP of 6.9°C gives an EAT of 995 degree days. After this time, the abalone were only just coming into condition. For this study on broodstock conditioning in green-lip abalone, a BZP of 6.9°C was assumed.

The aim of this study is to develop a sound protocol for conditioning broodstock abalone for commercial purposes by determining the most favorable conditioning period (e.g., 6, 8, 10 or 12 wks) as indicated by a visual condition index, histological assessment, spawning success rate (as a % of the group subjected to spawning induction), fertilization rate and hatch rate. Seasonal patterns for controlled and uncontrolled ("wildcat") spawnings and whether handling stress influences the success of broodstock conditioning and initial spawning success were also investigated. Gonad histology and macroscopic observation of the gonad were assessed as relative guides to the likelihood of spawning success.

METHODS

The term "conditioning" is used here for the process adopted to induce gonad ripeness and ability to spawn in captive adult abalone, usually outside of the normal spawning season but also to allow multiple spawnings within that season.

Experimental Set-up

The research was conducted at a commercial hatchery, Great Southern Marine Hatcheries (GSMH), Albany (117°57'38"E, 35°5'52"S), Western Australia. Wild abalone were collected from Bremer Bay, approximately 200 km east of Albany, and held in the conditioning system for up to 7 mo before the trial commenced, where broodstock were acclimatized and temperature control was refined. The trial ran for 36 wks from April 2001 to December 2001. The culture system consisted of 60, 30-L round plastic tubs, with 8 male tubs and 24 female tubs at 17.0°C \pm 0.4°C in the conditioning room, and 8 male and 8 female control tubs in an outdoor grow-out area to provide ambient conditions (e.g., natural photoperiod and temperature with unfiltered sea-water). The remaining 14 tubs of females were used for histology and were also held in the conditioning room at 17.0°C \pm 0.4°C. Each tub contained 5 abalone and males and females were held in separate tubs. The abalone used in this experiment were of mean shell length 118.1 mm mean size (range 87.5–142.1 mm total shell length) and 250.4 g whole weight (108.2–482.8 g).

The continuously aerated tubs had a flow rate of 1–1.5 L/min (\approx 2–3 water exchanges per hour) and a central standpipe. Water supplied to the reservoir (5,000 L) and heater/chiller unit was filtered down to 10 μ m using a bag filter. A photoperiod of 12 h low light and 12 h darkness was used for animals that were kept indoors.

Spawning Groups

All of the tubs except those set aside for histological examination were randomly assigned into 4 groups (6, 8, 10 and 12 wk spawning intervals). This is equivalent to \approx 420, 560, 700 and 840 EAT based on a BZP of 6.9°C. Over a 36-wk period, groups were spawned at 6, 8, 10 and 12 wk intervals respectively (Table 1).

TABLE 1.
Spawning schedule for each group of abalone.

Group	Spawning weeks (from day 0*)					
6 Week	6 (May)	12 (July)	18 (Aug)	24 (Sept)	30 (Nov)	
8 Week	8 (June)	16 (July)	24 (Sept)	32 (Nov)	—	
10 Week	10 (June)	20 (Aug)	30 (Nov)	—	—	
12 Week	12 (July)	24 (Sept)	36 (Dec)	—	—	

* Day 0 was the day when an attempt was made to spawn out all abalone after collection.

Each spawning group consisted of 6 female tubs and 2 male tubs from the conditioning room and 2 female tubs and 2 male tubs under ambient conditions (controls).

All animals were induced to spawn following commercial spawning protocols without being removed from their holding tubs. This strategy was aimed at minimizing handling of the abalone. Therefore for all spawnings, egg production was recorded per tub of 5 female abalone not per individual female. Animals from the histological examination group were not deliberately induced to spawn during the trial. Two tubs of females from this group were sacrificed every 4 wk for analysis by histology (see below).

Spawning success (%) was calculated for each planned spawning by:

Number of tubs of abalone that spawned \times 100 \div Total number of tubs of abalone that were subjected to spawning induction stimuli

Unplanned ("wildcat") spawnings also took place. As with data for planned spawnings in which the number of spawning inductions depended on the conditioning interval (6–12 wk), estimates of incidences of spawning and egg production had to take into account the number of tubs for each treatment (conditioned or control). Similarly data analysis by season also was corrected for the number of days of each season (Spring, Summer, Autumn, Winter) encompassed within the 36-wk trial.

Wildcat spawnings (%) for each month was calculated by:

Number of tub \times day combinations per month with evidence of wildcat spawnings \times 100 \div Number of days in month \times Number of tubs for control (=16) or conditioned (=32)

Similarly, wildcat spawnings (%) per season for each conditioning period and controls was calculated by:

Number of tub \times day combinations per month with evidence of wildcat spawnings \times 100 \div No of days in season \times Number of tubs for conditioning group (=8) or controls (=4)

Feeding and Cleaning

All individuals were fed daily *ad libitum* with a commercial formulated, extruded conditioning diet (Adam and Amos Feeds, South Australia). Feed was given as a rate of 1% to 2% body weight per day.

Each tub of abalone were cleaned daily (morning) with as little disturbance as possible. Complete drainage of each tub occurred three times a week. Every other day, tubs were just siphoned clean to minimize stress related to cleaning procedures. Rinsing water for the tubs was maintained at the same temperature as the culture vessels to eliminate possible spawnings from temperature shock.

Histology

Histological assessment was carried out on female greenlip abalone to determine progress with conditioning. Egg development was assessed every 4 wks, over a period of 24 wks, commencing April 11, 2001 by sacrificing two tubs of female abalone from the histological examination group and fixing them whole in 10% neutral buffered formalin. Gonad samples from the fixed samples for histology were cut from the abalone, dehydrated, embedded in paraffin wax, sectioned at 5 μ m and stained with hematoxylin and eosin using standard techniques. The gonads were examined and classified using the stages described in the abalone atlas produced by Handlinger et al. (2001). The stages they describe are 1 = Recovery phase gonads; 2 = Growing phase gonads; 3 = Mature ovaries; 4 = Atretic ovaries and 5 = Resting phase ovaries.

Handling to Assess Gonad Index

Throughout this experiment, abalone in the conditioning room, except those used for visual gonad index (below) and histology assessment, were never removed from their tubs. These tubs were used as the nonhandled control group for the assessment on handling versus nonhandling.

Every 14 days after the start of the experiment, two female tubs from each spawning group (6, 8, 10, 12 wk) were weighed, measured and visually assessed to determine the level of gonad ripeness. The same two tubs of animals were chosen each time to assess gonad ripeness, growth data over time and for the effects of handling. Abalone were removed by lifting them off the bottom with a spatula-like tool. The progression of gonad development was determined for each individual using a visual scoring system of 0–3 and was referred to as the visual Gonad Index (GI). A score of 0 = cannot determine the sex, 1 = the upper edge of the gonad was below the rim of the shell, 2 = the upper edge of the gonad was even with the rim of the shell, and 3 = the upper edge of the gonad was above the rim of the shell. This means that at a score of 1 the sex of the abalone can be determined, at a score of 2 there is a possibility the abalone may spawn and at a score of 3 it is assumed the abalone is highly likely to spawn. The egg production results were used to assess the influence of handling on spawning success, in comparison with the remaining 4 tubs of females from the conditioning room for each spawning group.

Experiment Initiation

All broodstock abalone used in the experiment were tagged and initial weight and shell length data were recorded. To initiate the experiment commercial spawning methods were used to induce spawning. All abalone were exposed to 18.5°C water temperature for 12 h, then desiccated for 45 min followed by an ultra violet (UV) treated water temperature shock of 21°C, which was slowly decreased back to 17°C over a period of 8 h. Animals were held in the UV treated water for a maximum of 24 h to induce spawning. After this time they were returned to their normal experimental conditions in the conditioning room or control area. The GI for each abalone were assessed and recorded during the desiccation time.

Data Recording

A temperature data logger was placed into the reservoir. Daily temperatures were also recorded manually. Water quality was checked weekly (DO, pH, ammonia and salinity). Atmospheric pressure readings were recorded on a daily basis.

Throughout the experiment any spawnings that occurred were recorded, including "wildcat" spawnings, which are spawnings that occurred unexpectedly throughout the trial. All results using data from "wildcat" spawning events excludes "wildcat" spawning data from the histology tubs. The natural spawning season for greenlip abalone was considered to be September to December. Where possible, numbers of eggs per tub and per group were recorded. Total number of eggs per batch was estimated from 3 sub-samples as:

Average number of eggs in 1-mL samples \times Total volume of the sample.

Data Analyses

Statistical analyses were carried out using the STATISTICA 6.1 (Stat Soft, Inc. 2002) computer package. The assumptions of normality and homogeneity of variance were confirmed graphically for each data set using box plots. Egg production data between conditioned and control tubs, and handled and non-handled tubs were compared with *t*-tests. Spawning success was also compared with *t*-tests between males and females. Spawning success, egg production and histological egg stages between conditioning intervals were analyzed using 1-way ANOVA. Relationships between the wildcat spawning and daily barometric pressure were explored using simple regression analyses.

RESULTS

Water Temperature and Quality

Water temperatures in the conditioning room were usually constant between 16.6°C to 17.2°C, whereas temperatures in the control tubs ranged from 14.0°C to 20.2°C (Fig. 1). Dissolved Oxygen ranged from 76.9% to 105.0% (mean 90.0%); pH was within the range of 7.78–8.29 (mean 8.17), whereas salinity was recorded between 35.2 ppt and 36.0 ppt with a mean of 35.5 ppt. Free ammonia concentrations were less than 0.1 mg NH₃-N/l.

Survival and Growth

Excluding abalone for histological assessment, high survival (>97%) was observed throughout the trial for all greenlip abalone held in the conditioning room and control area.

Mean average shell length for the conditioned and control tubs of abalone over the whole trial period of 36 wks was calculated at 6.03 μ m/day and 5.07 μ m/day respectively, whereas the mean

Figure 1. Average water temperatures in broodstock tanks in the conditioning room and in the ambient control area throughout the trial.

average weight gain per abalone for the conditioned and control tubs of abalone, were 30.80 $\mu\text{g/day}$ and 31.82 $\mu\text{g/day}$ respectively.

Spawning

In initiating the experiment no abalone actually spawned. However, wildcat spawnings (unplanned spawnings) had occurred in the majority of tubs within the 2 wks before initiating the experiment.

Wildcat spawning data for abalone held in the control groups showed that in April, outside of the natural spawning season, there were some wildcat spawning events occurring, whereas in May through to August, again outside the natural spawning season, there were very few wildcat spawning events (Fig. 2). However, in September through to December, during the natural spawning season, many more wildcat spawnings were recorded in both conditioned and control animals. For the planned spawning groups (every 6, 8, 10 and 12 wks), all wildcat spawning data showed similar patterns (Fig. 3). However, it was evident that more wildcat spawning events occurred in summer, within the natural spawning season in the controls (Fig. 3) despite the trial covering only 1 month in summer.

Planned spawning results showed that, over the whole trial period, egg production in the conditioned abalone was significantly greater than egg production in the controls ($df = 28$, $t = 2.299$, $P = 0.029$). Conditioned abalone produced 1.70 million eggs per female tub per planned spawning compared with abalone held in the control tubs that only produced an average of 0.40 million eggs per female tub (Fig. 4). Highest egg production was recorded within the winter months, outside the natural spawning season for abalone held in the conditioning room with an average of 3.16 million eggs per tub of 5 female abalone per planned spawning (Fig. 5). In comparison, for abalone held in the control tubs, the highest average egg production of 0.87 million eggs per tub of female abalone was recorded during spring (Fig. 5). Egg production from planned spawnings was lowest from abalone held in the conditioning room during the summer months (Fig. 5).

Results for the spawning intervals of 6-, 8-, 10- and 12-wk periods showed that abalone from the week 8 spawning interval had the highest egg production during the second spawning induction (week 16) of 44.23 million per tub of female abalone (Fig. 6). Egg production was very low in the first planned spawning attempt for spawning intervals of 6 and 8 wk of 2.5 million and 1 million respectively. However, spawning occurred in only about 13% of female tubs of abalone spawned during both inductions. For

Figure 3. Percentage of unplanned ("wildcat") spawning events that occurred in each spawning interval (6, 8, 10 or 12 wk) and control tubs of greenlip abalone for each season throughout the trial

spawning intervals of 10 and 12 wks the opposite was observed, with highest egg production of 23 million and 19 million occurring within their first planned spawning attempt and a decline in egg production for the following planned spawning attempts (Fig. 6). During the first planned spawnings, the percentage of female tubs in which abalone spawned were 75% and 38% for spawning intervals 10 and 12 wks respectively. For the latter inductions for these spawning intervals, where egg production declined, the percentage of actual spawnings also declined to 38% and 25% in both spawning intervals for the second and third spawning attempts.

Overall, the 6 wk spawning interval had the highest average percentage spawning success of 60%, whereas the 12-wk spawning interval had the lowest of 33% (Fig. 7). However, there was no significant difference between spawning intervals for spawning success ($df = 3$, $F = 0.164$, $P = 0.917$).

Average numbers of eggs produced for each interval showed week 8 to be slightly higher than intervals of 6, 10 and 12 wks with an average egg production of 12 million eggs produced per tub of 5 female abalone (Fig. 8). However, overall there was no significant difference between spawning intervals in terms of eggs produced per tub of female abalone ($df = 3$, $F = 0.150$, $P = 0.928$).

There was no significant difference ($t = 1.18$, $df = 38$, $P = 0.25$) between the percentages of males and females that spawned in each planned spawning induction.

No relationship was observed between wildcat spawning events and average daily barometric pressure ($r = 0.06$) or between wildcat spawning events and change in daily pressure ($r = 0.01$).

Fertilization and hatch rates were consistent between each spawning group throughout the trial. In general, all lines produced

Figure 2. Incidence of unplanned ("wildcat") spawning events that occurred in the conditioning and control tubs of greenlip abalone for each month of the trial.

Figure 4. Average number of eggs produced ($\times 10^6$) per tub of female greenlip abalone per planned spawning for the conditioned and control tubs of abalone over the trial period.

Figure 5. Average number of eggs produced ($\times 10^6$) per tub of female abalone per planned spawning for conditioned and control greenlip abalone for each season over the trial period.

from conditioned and control stock displayed very high fertilization (90% to 100%) and hatch rates (80% to 100%).

Histology

Egg stages expressed as percentage of mature (stage 3) gonads from the histological examination results were not comparable to the results obtained for GI (Table 2). However, egg stages over time showed a significant difference ($df = 6$, $f = 4.654$, $P < 0.001$). A significant drop was observed for the average egg stage between 0 and 4 wks ($P = 0.005$), whereas a significant increase for the average egg stage was evident between 4 and 16 wks ($P = 0.019$) as well as between 4 and 20 wks ($P < 0.001$).

Handling

Overall averages for egg production for the whole trial showed that nonhandled abalone produced more eggs (2.06 ± 0.68 million per tub of female abalone per planned spawning) than abalone from the handled group (0.98 ± 0.29 million) (Fig. 9). However, this difference was not significant ($df = 28$, $t = 1.459$, $P = 0.156$). Percentage spawning success rates for nonhandled and handled abalone were very similar and not significantly different, with values of 55% and 57% ($df = 28$, $t = 0.14$, $P = 0.889$).

DISCUSSION

Water Temperature and Quality

The broodstock conditioning system used provided stable water temperature and high water quality. In Albany, ambient water

Figure 6. Total number of eggs produced ($\times 10^6$) from planned spawnings for each conditioning period (6, 8, 10 or 12 wk) with greenlip abalone (data for handled, nonhandled and controls pooled).

Figure 7. Average percentage of tubs of greenlip abalone, per planned spawning (mean \pm SE), in which spawning occurred for each conditioning period (6, 8, 10 or 12 wk).

temperatures exhibit a smaller range and reach much warmer temperatures than in Tasmanian waters (Hindrum et al. 1996). At warmer temperatures it is evident that abalone grow faster (Freeman et al. 2000).

In the conditioning room a water temperature increase to 19.1°C in mid April and a decrease to 14.7°C in early September can be observed in Figure 1. These fluctuations corresponded to power failures to the heater/chiller unit.

Survival and Growth

All broodstock abalone showed high survival (97%) but low growth rates between the start and finish of the trial. There was very little difference between mean average weight gain and mean average shell length for both the control and conditioned tubs of abalone. The overall averages of 5.77 $\mu\text{m}/\text{day}$ for average shell length and 31.54 mg/day for average weight gain for broodstock abalone are slow when compared with growth rate estimates, used for stock assessment purposes, for wild adult greenlip abalone of 25 mm/year in southern Western Australia (A. Hart pers. comm.). Moreover, they are low when compared with growth rates observed for wild juvenile greenlip abalone of 1.690 $\mu\text{m}/\text{month}$ (Shepherd 1988). Shepherd and Hearn (1983) believe that energy expenditure during gonad development can reduce growth rate. Growth rate is affected by several variables including genotype (Brown 1991), density, type and amount of feed (Day & Fleming 1992), water flow (Higham et al. 1998), water quality (Harris et al. 1998) and handling techniques such as frequency of emersion (Maguire et al. 1996).

Figure 8. Average number of eggs produced ($\times 10^6$) from planned spawnings (including handled, nonhandled and controls) for greenlip abalone subjected to different conditioning periods (mean \pm SE).

TABLE 2.

Gonad index (GI) and percentage of mature egg stage (stage 3) for histology tissue sections averaged for 10 abalone, which were collected every four weeks over a period of 24 weeks.

Week	Average Gonad Index*	Average % of Mature Stages (Stage 3) for Each Week Histological Samples Were Taken
0	1.15 \pm 0.15	54.17 \pm 0.10
4	1.40 \pm 0.16	20.00 \pm 0.10
8	1.10 \pm 0.07	36.67 \pm 0.12
12	1.10 \pm 0.07	56.67 \pm 0.15
16	1.20 \pm 0.11	36.67 \pm 0.13
20	0.89 \pm 0.11	40.74 \pm 0.13
24	1.00 \pm 0.00	58.33 \pm 0.08

* For gonad index (GI) a score of 0 = cannot determine the sex, 1 = the sex of the abalone can be determined but spawning is unlikely, 2 = there is a possibility the abalone may spawn and 3 = it is assumed the abalone is highly likely to spawn.

Spawning

Within the 2 wks prior to the start of this experiment, wildcat spawning occurred in the majority of tubs of abalone. This could explain why we did not get any induced spawnings when all tubs of abalone were subjected to spawning stimuli at the beginning of the experiment.

Wildcat spawning data for abalone held in the control groups followed the general pattern of a natural spawning cycle for greenlip abalone. In the warm month of April there were some wildcat spawning events occurring, but in the cooler months of May to August there were very few wildcat spawning events. However, in the warmer months of September to December in the natural spawning season for greenlip abalone a lot more wildcat spawnings were evident (Fig. 2). Shepherd and Laws (1974) found the spawning season for greenlip abalone in South Australia to be October to March, whereas Wells and Mulvey (1992) concluded that it was September to December in Western Australia.

The results presented in this study show that greenlip abalone can be spawned outside of the natural spawning season. The egg production of conditioned broodstock from planned spawnings was highest before the natural spawning season commenced (Fig. 5). Fewer successful planned spawning events and lower egg production occurred around the natural spawning season. However, a high number of wildcat spawning events occurred in all tubs dur-

ing this period. Low egg production would be expected per tub of female abalone during the planned spawnings over the natural spawning season caused by abalone already expelling their eggs in unplanned spawning events.

Spawning events before the natural spawning season can be highly beneficial to farmers because they can take advantage of the enhanced growth of juveniles during the early summer months. Animals can be weaned off the plates before the highest summer temperatures occur. High water temperature during the weaning process can cause high mortalities in some regions of Southern Australia (M. Russell pers. comm.).

The planned spawning results showed that over the whole trial period the conditioned group of abalone produced around four times as many eggs as the control groups. This could partly be explained for 2 reasons. Firstly, the control groups did not produce many eggs in winter and secondly, a lot of egg production for the control group was "wasted" on wildcat spawnings (where egg production is not recorded). However, it still strongly suggests that holding broodstock abalone in a conditioning system has a major advantage over holding broodstock at ambient conditions. In recent years, most Australian farmers have held their broodstock in ambient conditions on their farm and only increased feeding and feed type to condition their broodstock. Many studies have suggested that holding abalone at constant temperature and feeding a good quality diet will condition broodstock abalone (Kabir 2001, Grubert & Ritar 2003, Leonart 1992, Moss 1998).

It was observed that the week 8 spawning interval produced a larger number of eggs per tub of abalone compared with all other spawning week intervals. The data for the first planned spawning for the week 8 spawning interval shows low egg production. This could suggest that most abalone in this group for the second planned spawning were actually conditioned for 16 wk and demonstrates the benefits of longer conditioning periods. This trial was only set to test a maximum interval of 12 wks. Further studies into longer conditioning times are now in progress.

Histology

Histological assessment of egg stages in greenlip abalone is more accurate in determining the maturity of the abalone than using the visual GI scoring system.

Histology results show a significant drop between 0 and 4 wks, suggesting that spawning or reabsorption of eggs may have reduced the average egg stage for that period. The significant increase in average egg stage between 4 and 16 wks and 4 and 20 wks suggests that the abalone come into condition around this time, which equates to 12 and 16 wks for conditioning. The need for a longer conditioning period for this species was also evident in Grubert and Ritar (2003), who found for greenlip abalone in Tasmania, egg production peaked when held at 18°C for 114 days (1265 EAT°C-days). Assuming the BZP of greenlip abalone is 6.9°C (Grubert & Ritar 2002) then this equates to approximately 18 wk at our trial temperature of 17°C. In another study in Tasmania, Leonart's adjusted results of 16 wks at 17°C, also shows that a longer conditioning period is needed (Leonart 1992).

In terms of the average number of eggs produced, weeks 6 and 8 were not very successful, which suggests that the abalone are not in condition after such short conditioning periods. Conditioning intervals of 10 and 12 wks appeared to be more successful. The first planned spawning for both the 10 and 12 wks intervals showed good egg production. The second and third planned

Figure 9. Average egg production ($\times 10^6$) per tub of female abalone (mean \pm SE) per planned spawning for nonhandled and handled greenlip abalone (data for conditioned and control tubs pooled).

spawning events for these two groups were not as successful because of high numbers of wildcat spawning events that appear to be uncontrollable in the warmer months of the year. Clearly, greenlip abalone do need at least 10 wks for conditioning.

Generally, most farmers use the GI as an indication of the abalone's spawning ability. However, results from the histological examination showed that visually inspecting the gonad was not a good indication of the actual level of gonad development. There is no evidence that the GI is a good indication of mature abalone eggs (Table 2). More recently, farmers have noticed that a large gonad does not necessarily mean that the abalone will spawn.

Handling

Handling abalone did reduce egg production within the trial but this was not statistically significant. The nonhandled abalone produced approximately twice the average number of eggs than abalone that were handled regularly throughout the trial. This may not have been statistically significant because of the difference in the number of replicates used for the handled and non-handled groups of 2 tubs and 4 tubs respectively. Potentially, there may not have been enough power to detect a significant difference. Hone et al. (1997) found that in the wild abalone near condition will spawn if high stress conditions occur. Abalone farmers have suggested that handling stresses abalone.

There was no difference between the percentages of males and

females that spawned in each planned spawning induction. This does not follow the same pattern that was described by Hahn (1989), that in the hatchery when males and females are induced to spawn, a higher percentage of males spawn compared with females. However, our observation that males generally spawned before females confirmed that of Hahn (1989). In this trial, males usually spawned before females and commenced about 11–12 h after induction with UV. Initially, spawnings had finished ~17–18 h after UV induction. However, later observations showed that there were 2 “periods” of spawnings, the first being early to late evening (~11–18 h after UV induction) and the second being around dawn (~24 h after UV induction).

This system is suitable as a commercial conditioning system as it reduces labor costs in handling and provides less stress to the abalone before spawning. However, in comparison it would be less suitable for genetic programs based on single pair crosses because the abalone are held in groups and not removed from the tubs before spawning.

ACKNOWLEDGMENTS

The authors thank the technical staff Gaynor Jones, Ian Cameron and Dianne Watson who maintained and assisted with spawning the abalone, the histology unit at the Department of Agriculture Western Australia for technical assistance in the processing of the histology samples and Dr Brian Jones who undertook the gonad staging from the histological slides.

INFLUENCE OF CONDITIONING DIET AND SPAWNING FREQUENCY ON VARIATION IN EGG DIAMETER FOR GREENLIP ABALONE, *HALIOTIS LAEVIGATA*

ABSTRACT Both nutrient provisioning of eggs, during development within the ovary, and egg diameter are believed to be important factors governing the development and survival of invertebrate larvae. The diet of female broodstock and the conditioning regimen are likely to influence these parameters. In this study we examine the effect of broodstock diet (three formulated diets differing in levels of the fatty acid, Arachidonic acid [ARA], and a red seaweed diet) and spawning frequency on egg diameter variability both within a batch of eggs spawned from one female and between batches of eggs. Greenlip abalone broodstock were spawned at the beginning of the experiment and again every 16 wks (1131°C days effective accumulative temperature [EAT]) using commercial hatchery practices. The variability of egg diameter within batches spawned from the same female over three consecutive spawning rounds and within diet treatments was determined. Cytoplasm diameter, vitelline layer and jelly coat thickness of unfertilized eggs were also compared between eggs spawned from individual females and between females. In addition, the relationships between broodstock parameters (weight and shell length) and egg diameter were explored. Eggs spawned from females feeding on a red seaweed diet were smaller than eggs from the low ARA treatment. Depending on spawning frequency, broodstock diet can influence the cytoplasm diameter and jelly coat thickness. No relationship between egg diameter and broodstock parameters was found. However, batches spawned from the same female abalone became more variable over time with a shift in size frequency distribution. Results indicate that the variability of egg diameter within a batch changes from female to female and highlights the importance of selecting successful broodstock for conditioning at commercial hatcheries.

KEY WORDS: abalone, *Haliotis laevigata*, diets, egg diameter, arachidonic acid

INTRODUCTION

One of the crucial factors controlling the development of the Australian abalone aquaculture industry is the successful conditioning of broodstock because the supply of suitable wild broodstock has at times been limiting. Gonad conditioning provides flexibility in production cycles and more economical use of hatchery resources (Leonart 1992) as well as allowing genetic improvement programs.

Abalone larvae are lecithotrophic and rely heavily on yolk reserves provided by the egg to fuel development (Jaekle & Mahan 1989). Previous studies have indicated that smaller eggs have improved fertilization rates and contain more total lipid than larger eggs (Daume & Ryan 2004). However, it is widely considered for invertebrates, that larger eggs produce larger offspring with a greater chance of survival (Leviton 2000), and that fertilization is increased at lower sperm concentrations for larger eggs (Leviton 1996, Marshall et al. 2002).

It has been proposed that the most appropriate method of determining reproductive cycles in molluscs and echinoderms is to measure oocytes (Grant & Tyler 1983). However, egg diameter, post spawning, is believed to be a key determinant of reproductive performance (Brooks et al. 1997) and small differences in egg diameter are considered to have significant biological consequences (George 1999). The ratio of cytoplasm to egg diameter is considered to be useful for assessing reproductive performance in blacklip abalone, *Haliotis rubra* Leach, (Littay & De Silva 2001) and to provide a measure of optimal egg size for fertilization experiments without the need for histological examination.

Earlier research on broodstock conditioning with greenlip abalone (*Haliotis laevigata*, Donovan) showed evidence of nutrient depletion of eggs during lengthy conditioning periods and high

spawning induction frequency (Daume & Ryan 2004, Freeman et al. submitted).

Thus nutrient provisioning of eggs and egg diameter are important factors governing the development and survival of larvae. The diet of female broodstock and the conditioning regimen are likely to contribute to the quality of abalone eggs.

A crucial step in successful abalone aquaculture is selecting female broodstock that exhibit high fecundity and produce high quality eggs over consecutive spawnings. This reduces the need to hold large groups of females and minimizes the amount of hatchery resources, such as feed, needed to maintain the broodstock.

This study examined the effect of diet (three formulated diets with differing levels of the fatty acid, ARA and a red seaweed diet) and spawning frequency on the variability in egg diameter within a batch of eggs spawned from one female and between batches and is part of a larger study of the influence of these diets on fecundity, egg quality and larval success.

MATERIALS AND METHODS

Broodstock Conditioning

Greenlip abalone, *Haliotis laevigata*, were collected in August 2003 from Augusta (115°16'E; 34°32'S) and Hopetoun (120°13'E; 33°55'S), Western Australia and held indoors at Great Southern Marine Hatcheries, Albany, Western Australia.

Broodstock were randomly assigned to spawning groups (A to D), and within each spawning group there were 12 round 60 L plastic tubs of females and two tubs of males, with each tub containing 3 animals.

Broodstock were exposed to a photoperiod of 12L:12D at ca. 100 lux (measured at the bottom of tubs). The conditioning system received flow through, temperature controlled seawater (average temperature, 17 ± 0.2°C).

Broodstock (average length 132.5 ± 3.5 mm; average weight

*Corresponding author. E-mail: fgraham@fish.wa.gov.au

352.2 ± 27.6 g) were spawned prior to treatment conditioning and again every 16 wks. (i.e., every 1131°C-days EAT). The study was conducted from October 2003 to October 2004 including a natural spawning season.

EAT was calculated using the formula (Kikuchi & Uki 1974):

$$Y_n = \sum_{i=1}^n (t_i - \theta)$$

where Y_n (°C days) = EAT, n (days) = number of days since water temperature rose above θ , t_i (°C) = daily water temperature in which the animal was reared, and θ (°C) = biological zero point for gonad maturation (6.9°C for *H. laevis*; Grubert & Ritar 2003). Spawning dates were October 2003 for the spawn out, January/February 2004 for the first, May/June 2004 for the second and September 2004 for the third spawning (Table 1).

Within each spawning group (Table 1), 36 females (9 females per treatment) and 6 male greenlip abalone were individually induced to spawn using a combination of desiccation for 1 h, heat stress at 21°C and UV treated seawater.

Diet

Female broodstock were conditioned on four different diets, with three replicated tubs (9 animals in total) per diet treatment and per spawning group. One set of females were fed a formulated diet with a low enrichment level of arachidonic acid (EPA: ARA = 3:8; 1% of total fatty acids), the second set was fed a formulated diet containing a high level of ARA (EPA: ARA = 1:16; 2% of total fatty acids). A third set was fed a formulated diet containing no arachidonic acid (EPA: ARA = 6:0; 0% of total fatty acids). The formulation of the diet is proprietary. The fourth set of females was fed a mixed red seaweed diet (e.g., *Plocanium mertensii*, *Gracilaria* sp.). The mixed red seaweed was collected from the Southern Ocean mainly around Albany (117°95'E; 34° 90'S); the *Gracilaria* sp. was collected from Hopetoun (120°13'E; 33°95'S). Animals were cleaned and fed *ad libitum* daily. Feed intake was monitored daily.

Egg Measurements

Unfertilized egg samples were collected within 30 min of the female spawning and immediately fixed in 10% formalin. Thirty eggs were then measured using an eyepiece graticule on an inverted microscope. Cytoplasm diameter, vitelline layer and jelly coat thickness were compared between individual females, diet treatments and across consecutive spawnings (Fig. 1). The variability of egg diameter within batches spawned from the same female over three consecutive spawning rounds and within diet treatments were determined. Egg diameter includes the vitelline and cytoplasm components of the egg. The ratio of cytoplasm to egg diameter was calculated as the cytoplasm measurement di-

Figure 1. Position of cytoplasm, vitelline layer and the jelly coat in unfertilized eggs from *Haliotis laevis*. Total egg diameter includes the cytoplasm and vitelline layer.

vided by the egg diameter. Eggs were classed as primary eggs when the jelly coat and vitelline layer was absent and the total egg diameter was on average 111.51 ± 10.54 µm.

Data Analysis

All data analyses were carried out using Statistica software (version 6.0, StatSoft, Inc. 2002). Normality of all data was checked graphically using boxplots and with the Kolmogorov-Smirnov test.

Comparisons of egg parameters (cytoplasm, vitelline layer and jelly coat thickness), and comparisons of broodstock parameters with hatch and egg size, were carried out using analysis of variance (ANOVA) with Tukey *post hoc* comparisons. Repeated measure analyses could not be performed, because different individuals spawned successfully during each of the three attempted spawnings.

Weight and shell length data in relation to weight loss were investigated using repeated measures ANOVA and Tukey *post hoc* comparisons. The relationship between broodstock parameters (length and weight) and egg diameter were explored with a simple regression analysis ($P < 0.05$).

Size-frequency distribution of egg diameter were compared over time and between treatments where appropriate using descriptive statistics (minimum, maximum, size range, first and third quartile). Interquartile differences between the first and third quartile were used as a measure of spread of the size-frequency distributions.

TABLE 1.
Spawning dates for each spawning group.

Spawning events	Spawning groups			
	A	B	C	D
Spawn out	07.10.03	15.10.03	22.10.03	29.10.03
First spawning	26.01.04	03.02.04	11.02.04	18.02.04
Second spawning	19.05.04	23.05.04	31.05.04	08.06.04
Third spawning	08.09.04	14.09.04	22.09.04	29.09.04

TABLE 2.

Influence of diet on cytoplasm diameter, vitelline layer and jelly coat thickness of abalone, *Haliotis laevigata*, eggs and the presence of primary eggs over three consecutive spawning periods (1, 2 and 3). (Data are means (μm) \pm SE)

Diet	Spawning	Cytoplasm	Vitelline	Jelly coat	Egg diameter (μm)	Ratio of cytoplasm to egg diameter	Percent occurrence of primary eggs (%)
Red seaweed	1	194.39 \pm 1.52 ^a	18.17 \pm 0.90	117.53 \pm 3.89 ^a	212.52 \pm 0.90	0.92	0.18 \pm 0.13

RESULTS

Influence of Diets on Cytoplasm Diameter, Vitelline Layer and Jelly Coat Thickness, Egg Diameter and the Ratio of Cytoplasm to Egg Diameter of Abalone Eggs over Three Consecutive Spawning

During the first spawning, diet had a significant effect on cytoplasm diameter and jelly coat thickness ($df = 9$, $F = 2.13$, $P = 0.03$), however there was no significant difference in vitelline thickness between treatments (Table 2). Eggs obtained from females fed the red seaweed diet were smaller in cytoplasm diameter than the low ARA treatment ($post\ hoc = 0.005$). Jelly coat diameter was largest in the red seaweed treatment and significantly larger than in the low ARA treatment ($post\ hoc = 0.007$).

Diet treatments were found to have no significant effect on cytoplasm diameter, vitelline layer or jelly coat thickness of eggs obtained from the second ($df = 9$, $F = 1.102$, $P = 0.38$) and third consecutive spawning ($df = 9$, $F = 1.12$, $P = 0.35$).

Across all spawnings, diet significantly influenced egg diameter ($df = 3$, $F = 3.24$, $P = 0.023$). Egg diameter in the red seaweed diet was significantly smaller than egg diameter in the low ARA ($post\ hoc = 0.015$), but did not differ significantly from the high ARA or control diet.

In all four diet treatments, the ratio of cytoplasm to egg diameter decreased between the first and third spawning rounds. The ratio was highest in the low ARA treatment during the first spawning round and decreased to 0.88 in the third spawning round. Similarly the ratio in the high ARA treatment decreased to 0.88 in the third round, from 0.92 in the first round and 0.90 in the second round.

The occurrence of primary eggs in batches spawned by females fed the red seaweed diet increased over the three consecutive spawning rounds (Table 2). However, primary eggs occurred more frequently in the three formulated diet treatments, particularly during the first spawning round.

Relationship Between Diet, Shell Length, Weight and Weight Change of Female Broodstock over Three Consecutive Spawning Rounds

Table 3 shows the shell length, weights and weight changes of all female broodstock at each individual spawning including the

initial spawn out. Over the whole experimental period, all animals lost weight and time had a significant effect on weight loss ($df = 3$, $F = 11.78$, $P = 0.00$). Broodstock weight at spawnout was significantly higher than weight during the first ($post\ hoc\ P < 0.001$), second ($post\ hoc = 0.000133$) and third ($post\ hoc\ P < 0.001$) spawnings.

Size Frequency Distribution of Eggs Spawned by the Same Female over three Consecutive Spawning Rounds

Red Seaweed

Eggs spawned by female one during the first spawning ranged between 208–229 μm , with 75% (3rd quartile) of the eggs being within 210 and 224 μm in diameter (Table 4, Fig. 2a). The spread

TABLE 3.

* Means, within a column, with different superscript letters are significantly different ($p < 0.05$).

of data became slightly more variable during the second spawning increasing to an interquartile difference of 7.23 from 5.26 during the first and third spawning. For the second female, variability in egg size decreased from the first to the second spawning and then increased slightly during the third spawning (Interquartile difference 7.23, 2.63 and 5.92 respectively). The spread of data for the third female was more consistent over all three spawnings with the interquartile difference remaining at 5.26. Egg diameter ranged between 210–230 μm .

High ARA

Eggs obtained from this female fed the high ARA formulated feed were less variable over time, with eggs ranging between 203–221 μm during the first spawning and between 210–230 μm and 210 and 229 μm in the second and third spawnings, respectively (Table 4, Fig. 2b). The interquartile difference stayed constant at 5.26 during all three spawnings.

Low ARA

The size frequency distribution of eggs obtained from the first female were highly variable between the first and second spawnings, with the distribution shifting from between 200–253 μm , respectively (Table 4, Fig. 2c). The interquartile difference increased from 2.63–15.78 from the first to the second spawning and decreased to 6.57 during the third spawning. The second female only spawned during the first and second spawning, however the size variability was smaller and ranged from 210–239 μm .

Control Diet (No ARA)

During the first spawning round eggs obtained from the first female ranged between 204–228 μm with 75% (3rd quartile) of the eggs within 205 and 218 μm in diameter (Table 4, Fig. 2d). The interquartile difference decreased slightly from 6.25–5.26 during the second spawning round, and was highest at 11.84 during the third spawning round. The eggs spawned by the second female were less variable during the first and third spawning. The interquartile difference was lowest during the first spawning (5.59) and increased to 7.89 and 7.56 during the second and third spawning respectively. The third female spawned during only the first and second spawning however, egg size decreased over these time periods with eggs ranging from 210–224 over the first and second rounds, respectively.

DISCUSSION

Influence of Diets on Broodstock Parameters and Egg Parameters

The results of this study suggest that diet is not the only factor controlling the size of the eggs produced. Over all three consecutive spawnings, egg diameter in the red seaweed treatment differed significantly from only the low ARA diet, and relative differences varied with spawning rounds. During the first spawning round, eggs spawned by females fed the red seaweed diet were significantly smaller in cytoplasm diameter and had significantly larger jelly coats than those in the low ARA treatment. However, during the second and third consecutive spawnings there was no significant effect of diet on cytoplasm diameter, vitelline layer thickness or jelly coat thickness. Previous studies have indicated that diet directly influences egg quality in marine invertebrates (Jaekle 1995). On the other hand, Nevejan et al. (2003) found that the total lipid content of eggs and the size of the eggs spawned by the

scallop, *Argopecten purpuratus* were independent of diet. Similarly Caers et al. (2002) found there to be no significant effect of diet on the egg size of the oyster, *Crassostrea gigas*.

The role of diet in this study is unclear. Whether the increase in egg diameter in the low ARA treatment is correlated with the ARA content of the eggs will be determined after subsequent biochemical analysis of the eggs. It is likely however that the maternal condition of the female broodstock during the second spawning was negatively influenced by some other factor like overall animal nutritional condition. All animals lost weight during the experiment particularly when feeding on the formulated diet at the start of the experiment. It could be suggested that animals needed a

weaning period to get used to the new diets because weight loss was less apparent on the natural diet and decreased on the formulated diets after the first spawning.

If measurements of egg diameter are an accurate representation of egg ripeness, because larger eggs are more ripe than smaller eggs, then those eggs obtained from the low ARA formulated feed treatments were more ripe than those obtained from the red seaweed treatment. On the other hand the low ARA diet showed the highest percentage occurrence of primary eggs. It is possible that these larger eggs contained more moisture as found by Daume and Ryan (2004) and were thus not a true reflection of ripeness. It may also be that the micronutrient content of the formulated feeds may be lower than optimal. The red seaweed diet is a mixed species diet and subsequently may be lacking in some macronutrients. However, eggs in the red seaweed treatment showed the lowest percentage occurrence of primary eggs. A follow up study investigating combined broodstock conditioning diets, where broodstock are first fed a low ARA formulated diet and then finished off with red seaweed before spawning, is planned.

The decrease in the ratio of cytoplasm to egg diameter across all treatments may suggest that egg quality deteriorated over the consecutive spawnings. Littay and De Silva (2001) reported for blacklip abalone, that a ratio of yolk (equivalent to cytoplasm in this study) to total egg diameter between 0.83–0.87 was ideal for this species and provided the highest fertilization rate. These authors suggested that any deviation from this range (0.83–0.87) indicates overripe eggs or declining egg biochemical status. The ratios found in our study were much higher than those found by Littay and De Silva (2001) however that might be attributable to the different species investigated in this study.

Size Frequency Distribution of Eggs

The descriptive statistics of the size frequency distributions of eggs spawned from individual females suggest that the eggs within the gonad are not uniform in size and display high variability between consecutive spawnings. This may be directly related to conditioning time, with the broodstock needing a longer conditioning period to produce eggs of similar size and quality.

Huchette et al. (2004) found that development of blacklip abalone oocytes within the gonad was not uniform and resulted in eggs that were variable in size. Clavier (1992) suggested that only the largest and ripest oocytes within the gonad are released during a spawning. However, in this study egg size was very variable over single spawnings for some females. Broodstock may have responded to nutritional stress, resulting in resorption of ripe gametes. Martinez et al. (1992) concluded that a reduction in the gonad index of a hatchery-reared scallop, *Argopecten purpuratus*, was caused by resorption of ripe gametes because the broodstock were under nutritional stress.

In this study, egg diameter was measured as total egg diameter including the vitelline layer and the cytoplasm. However, according to Grant and Tyler (1983), the most appropriate method of determining reproductive cycles in molluscs and echinoderms is to measure oocytes. On the other hand, egg diameter is believed to be a key determinant of reproductive performance in fish (Brooks et al. 1997) and small differences in egg diameter are considered to have significant biological consequences (George 1999). Measuring egg diameter of unfertilized eggs (post spawning) is a relatively quick and simple means of gaining reproductive information about broodstock without the need of culling broodstock to measure oocytes.

CONCLUSION

In this study we showed that the egg diameter varied between eggs spawned from females (*H. laevigata*) feeding on a red seaweed compared with the low ARA diet. Depending on spawning frequency, broodstock diet can also influence the cytoplasm diameter and jelly coat thickness. Egg parameter measurements and ratios of cytoplasm to egg diameter may be useful parameters for assessing reproductive performance in greenlip abalone. Studies are needed to further investigate the influence of broodstock diets on egg variability and ultimately on larval survival. Combination diets, where broodstock are fed a formulated feed for the better

part of the conditioning period, and then a suitable red seaweed species will be tested.

ACKNOWLEDGMENTS

The authors thank Great Southern Marine Hatcheries, Australia for hosting this part of the study and their staff and Kylie Freeman, Mathieu Castex and Misty Shipway for helping with spawnings and abalone egg measurements. Drs Greg Maguire and Anthony Hart provided useful editorial input. This study was funded as part of an FRDC project (2003/203). Dr Brett Glencross formulated the broodstock diets and he and Wayne Hawkins produced the diets.

GROWTH, MORTALITY, RECRUITMENT AND SEX-RATIO IN WILD STOCKS OF SILVER-LIPPED PEARL OYSTER *PINCTADA MAXIMA* (JAMESON) (MOLLUSCA: PTERIIDAE), IN WESTERN AUSTRALIA

ANTHONY M. HART* AND LINDSAY M. JOLL

Western Australian Fisheries and Marine Research Laboratories, PO Box 20,
North Beach, WA 6920, Australia

ABSTRACT Growth, mortality, recruitment and sex-ratio of wild stocks of the silver-lipped pearl oyster *Pinctada maxima* were studied at sites spanning the geographic extent of the commercial fishery using mark-recapture experiments, recruitment cohort analysis and research surveys of stock abundance and reproductive status. Growth parameters (L_{∞} , K) from the von Bertalanffy growth equation were estimated at 210 mm dorso-ventral measurement (DVM) (± 16 mm SD) and 0.74 at the Lacepede Islands, L_{∞} of 199 mm DVM (± 6 mm SD) and K of 0.79 on 80 Mile Beach, and L_{∞} of 194 mm (± 6 mm SD), and K of 0.72 at Exmouth Gulf respectively. Estimates of natural mortality (M) by tagging were very low (0.02–0.03), compared with catch-curve analysis, which estimated M to be between 0.1 in deeper (30–34 m) populations and 0.18 in shallow (9–12 m) populations. Settled *P. maxima* spat (0 + and 1 + age classes) on adult shell were quantified (e.g., 1,317 spat found on 119,000 shell in 2003) to obtain an annual recruitment index, which showed clear temporal trends in abundance. Over 7 y (1992 to 1995; 2001 to 2003) the annual recruitment index varied from 5.1–8.0 spat per 1,000 shell for the 0 + age class, and 3.5–6.2 spat per 1,000 shell for the 1 + age class. Preliminary predictions of future abundance showed promise, however more work is required on spatial and habitat effects on spat settlement before the potential of the 0 + and 1 + recruitment indices can be realized. We also confirm that Western Australian populations of *P. maxima* are protandrous hermaphrodites, with a 50:50 sex ratio not achieved until females are 170 mm DVM, which is above the maximum size fished.

KEY WORDS: pearl oyster, *Pinctada maxima*, growth, mortality, recruitment, sex-ratio

INTRODUCTION

Wild stocks of *Pinctada maxima* (Jameson) underpin an AU \$120 million dollar pearling industry in Western Australia and the fishery has been in operation for over 120 y. From the late 1880s up to the mid 1990s, the industry relied primarily on wild caught shell for pearl production. Since then, a concerted shift towards the culture of *P. maxima* led to the determination of the reproductive cycle of stocks (Rose et al. 1990), techniques for larval and spat culture (Rose & Baker 1994) and the assessment of growth and mortality in hatchery and nursery culture (Mills 2000, 1997, Taylor et al. 1997, Yukihiro et al. 1998). This focus on the cultured animal is not surprising; with the exception of Western Australia, there are no substantial wild stocks left anywhere in the Indo-Pacific. Even the estimation of spat settlement and recruitment of wild stocks has been primarily directed towards the potential of farming wild-caught spat for pearl production (Beer & Southgate 2000, Knuckey 1995). Knuckey (1995) suggested that artificial collectors of natural spat could be used as a stock assessment tool, as is the case in scallop fisheries. However, early trials determined that logistical difficulties (12 m tidal ranges) associated with the deployment of artificial spat collectors precluded their satisfactory application in Western Australia (Joll 1994).

In the 1950s, Takemura and Okutani (1955, 1958) identified the “piggyback spat” phenomenon, whereby new recruits of *Pinctada* sp settled on the backs of adult oysters and remained attached for at least the first year or two of their life. Given that over half a million oysters are caught each year in the fishery, we hypothesized that “piggyback spat” sampled from the wild caught shell may provide a useful broad scale index of recruitment in this species. The rate of “piggyback” spat found on pearl oysters caught by the commercial fishery was examined for its potential as a method for monitoring and measuring recruitment to the pearl

oyster stock. This provides a basis for understanding the annual variation in recruitment and predicting the level of recruitment to the fishery 2–3 y later. The current recruitment index is based on oysters reaching legal minimum size (120 mm shell length) and can include a combination of year classes.

Despite the long-history of exploitation of this pearl shell, there have been no published estimates on key demographic parameters of wild stocks. The aims of this study are therefore, to provide comprehensive estimates of growth, mortality, recruitment and sex-ratio in commercially harvested wild stocks of *P. maxima*.

MATERIALS AND METHODS

Growth

Growth was assessed with data from different stages of the life history; growth-increment measurements from tag-recapture experiments at the northern (Lacepede Islands), central (80 Mile Beach) and southern (Exmouth Gulf) areas of the commercial fishery (Fig. 1), and cohort analysis of the 0 + and 1 + age classes in successive years. Oysters for the tag-recapture experiment were obtained from commercial and research diving. Prior to measurement and tagging, oysters were held in plastic holding crates hung from the side of the boat or aerated seawater on deck (<4 h) or when available, in purpose built seawater through-flow tanks on pearling boats (up to 12 h). All releases and recaptures were made during a single neap (tide) in June of each year at the 80 Mile Beach site, during a single neap in February/March each year at the Lacepede Channel site and during a single neap in June/July each year at the Exmouth Gulf site. Overall, annual growth increments from 2,700 recaptured animals (Table 1), combined with modal length frequency of 0 + and 1 + cohorts over 8 years were used in the determination of growth of *P. maxima*.

Oysters were tagged using plastic shellfish tags (Hallprint, South Australia) measuring approximately 15 × 7 mm (7 × 3 mm for smaller oysters <50 mm DVM). These tags were applied to the

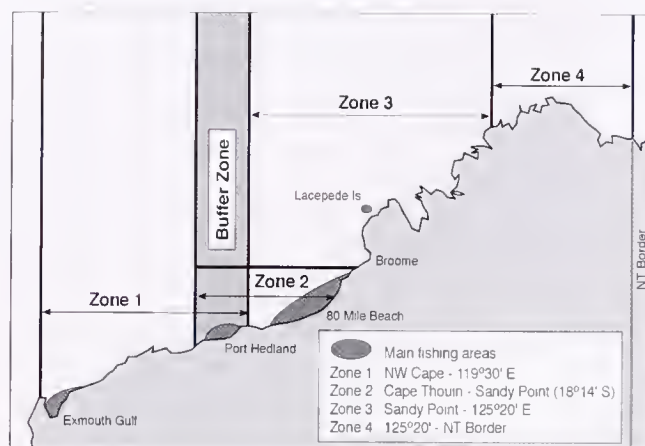

Figure 1. Management areas of the Western Australian *Pinctada maxima* fishery showing the three populations examined for growth (Exmouth Gulf, 80 Mile Beach, Lacepede Islands). The buffer zone is the area in which license holders in both Zone 1 and Zone 2 may harvest pearl shell.

left and right valves of each oyster using a cyano-acrylate glue (Selleys or Loctite 454 Gel). Each oyster was tagged using a pair of tags with the same 4 character identifier. The dorso-ventral measurement (DVM) of each oyster was recorded using standard calipers and measuring boards. Other morphometric measurements (anterior-posterior, hinge line, hinge depth and thickness) were taken, but only the DVM results are reported here.

Oysters were released on commercially fished habitat characteristic of each region. At the 80 Mile Beach site and Lacepede Channel, oysters were released in 15–18 m depth; at Exmouth Gulf oysters were released in 5–8 m. Oysters recaptured during research surveys were remeasured in successive years and rereleased in the same area. Any new pearl oysters found during recapture surveys were tagged, measured and released along with the recaptured oysters. During the period of growth monitoring, the pearling industry avoided fishing in the vicinity of tag sites.

Growth was analyzed using a maximum likelihood reformulation of the Von Bertalanffy growth curve for tagged data (Francis 1988). Equations 1 and 2, and Table 2 of Francis (1988) describe the reformulated equations and parameters. Model fitting is conditional on specifying two appropriate lengths described by the data (α and β), from which mean annual growth (g_α , g_β) and K and L_∞ is calculated and the resultant fit examined. The best fit (maximum log-likelihood) for the *P. maxima* growth model occurred with the following values of α and β for each region. Lacepede

Islands (50, 170 mm DVM), 80 Mile Beach (60, 160 mm DVM) and Exmouth Gulf (65, 180 mm DVM). We also use the variability in growth-increment data to estimate the standard deviation of L_∞ , as described by Francis (1988).

Mortality

Pearl shell fishing in Western Australia is a gauntlet fishery targeting 3 age classes (3–6 y olds) in the 120–170 mm DVM size range, with larger animals unexploited. Natural mortality was determined directly and indirectly for the unexploited portion of the stock (shell >170 mm DVM) by tag and recapture studies conducted on fixed transect lines and by examining stock size-structure and undertaking length converted catch-curve analysis (Pauly 1984).

Mortality: Tagging Data

Pinctada maxima were placed in a predefined grid area and monitored at successive time intervals. Five parallel lines were established at 6-m depth in the Gales Bay area of Exmouth Gulf in July 1998. The lines were secured at the ends with anchors along a north-south direction approximately 10 m apart, and numbered 1–5 from east to west. Short lengths of chain were attached to the rope at regular intervals to assist in anchoring each line to the bottom. Oysters were collected from surrounding stocks, brought to the surface, placed in baskets suspended in the water from the side of the boat and tagged and measured as described in the growth section. The number of shell collected, processed and placed on the bottom each time was minimized (approximately 40–50), to ensure the pearl oysters were stressed as little as possible from the catch and tag procedure. Oysters were then hand placed on the substrate next to one of the five lines on the seabed.

A total of 721 oysters were tagged and released between July and August 1998. The size range tagged was 60 mm to 240 mm DVM, with over 75% of shell being greater than 170 mm.

To separate natural mortality from experimental mortality (oysters stressed by the collection and translocation to experimental sites), shell were allowed to recover for 1 mo after the initial tag and release. Experimental mortality was estimated for the 1-mo period, after which the estimation of natural mortality began. It was assumed stressed shell would either have died or recovered to a naturally healthy state after a month.

The intention was to collect mortality data after pearl oysters had been at liberty for 1 and 2 y (August 1999 and 2000). However, during the first assessment of the experiment (August 1999), the destructive effects of a category 5 cyclone (Vance, March, 22 1999), which produced Australia's highest ever recorded wind gust of 273 km/h, became apparent. Experimental lines suffered a similar fate to equipment on nearby commercial farms, where 395 mm of rainfall run-off, high winds, and storm surge had caused widespread movement of oysters and equipment. Overall survival rate of shell was quite high, as a large number of pearl oysters were found alive ($n = 221$, 48%), however there was no discernable structure left to the experimental layout and results obtained were not deemed representative of a normal year.

Consequently, a repeat experiment was set-up in Exmouth Gulf on the August 8, 1999 to determine survival of shell over a single year period. Seven clumps of 20 tagged shell spaced approx 0.8 m apart, were positioned by divers along four 50-m lines (Fig. 2). The experiment sites were revisited a year later when divers retrieved, recorded and measured the tagged oysters. This sampling layout simulated the natural distribution of shell on the bottom.

Figure 2. Design of mortality study site in Gales Bay, Exmouth.

Mortality: Length-converted Catch Curves

Length-converted catch curve analysis was used to estimate natural mortality in the unfished portion of the population above 170 mm. First, age-length keys were generated from the parameters of the von Bertalanffy growth equation, with variations of age at length obtained from the residuals in the tag-recapture model fitting (Haddon 2001). Second, shell lengths from research surveys of the northern (Lacepede Channel and Hama Patch) and 80 Mile Beach populations (5 locations: Patterson Shoal, 10 Mile, 13–15 Mile, 17 Mile, Compass Rose) were allocated to ages using proportions in the age length key. No model was run for oysters in Exmouth Gulf because there was no detailed survey of these stocks to provide length frequency information.

Natural mortality (M) was assessed by determining the negative slope of the regression line from log frequency estimates of numbers at age for those shells above 170 mm (Pauly 1984). Mortality was estimated for 4 locations (Lacepede Islands, 80 Mile Beach Inshore, 80 Mile Beach Offshore, Compass Rose).

Recruitment

Research and industry personnel inspected oysters collected by pearl divers for the presence of settled *P. maxima* spat, which were separated into two age classes (Fig. 3). After each drift, between 100 and 300 shell were caught and placed in a central pile for cleaning. Twenty oysters at a time were randomly selected from the pile, each one inspected, spat collected and measured, and the process repeated until a representative subsection of the catch had been sampled. Between 18,000 (1991) and 137,000 (2001) adult pearl oysters were examined each year for the presence of spat (Table 2). Currently, this sampling effort evaluates 25% to 30% of oysters caught each year. A comparison of spat abundance between research and industry data was also undertaken.

Sex Ratio

Rose et al. (1990) and Hancock (1993) quantified the reproductive cycle of wild stocks of *P. maxima* in Western Australia, and our sampling utilized this knowledge to determine the population sex-ratio. To coincide with the beginning of the predicted spawning season, sex-ratio data were examined from oysters collected from 80 Mile Beach in October 1998 ($n = 479$). DVM of all specimens was recorded and the valves of each oyster were partially opened to inspect gonad condition and determine gender by visual inspection of gonad color (males, white to cream colored gonad; females, pale yellow to orange colored gonad). Animals in which the gonad was a watery white color or appeared translucent were recorded as indeterminate. Sex-ratio variation by size was examined.

RESULTS

Growth

Pinctada maxima obtains an average maximum theoretical length of between 193 and 210 mm DVM, and a von Bertalanffy growth coefficient (K) of 0.72–0.79 (Table 3). Growth curves and residual analysis of model fits describing growth in *P. maxima* are shown in Figure 4. Oysters grow faster and attain a higher maximum size in the Lacepede Islands, in comparison with the 80 Mile Beach and Exmouth Gulf stocks.

A comparison of length frequency of the commercial catch and research surveys for both populations (Lacepede Islands

Figure 3. *Pinctada maxima* spat found on commercially fished adult shell. (A) O + spat, 17 mm DVM, approximately 4 mo old; (B) 1 + spat, 57 mm DVM, approximately 16–18 mo old.

and 80 Mile Beach) confirms the growth curve results, namely a larger size of *P. maxima* at the Lacepede Islands (Fig. 5).

Spat cohort data shows growth to be relatively slow in the first 18 mo, with average annual increment between 0+ and 1+ cohorts varying from 28–36 mm, the exception being 1995, which at 42 mm, appears to have been an exceptionally fast growth year (Fig. 6).

TABLE 3.

Growth parameters and their variability for the silver-lipped pearl oysters (*Pinctada maxima*) at three locations in Western Australia.

Growth Parameters ¹	Lacepede Islands	80 Mile Beach	Exmouth Gulf
α (mm)	50	60	65
β (mm)	170	160	180
g_{α} (mm year ⁻¹)	42	30	37.5
g_{β} (mm year ⁻¹)	10	8	9.5
L_{∞}	210	200	194
Standard deviation of L_{∞}	5.0	16.2	5.3
K	0.74	0.79	0.72

¹ The parameters are derived from the Francis (1988) reformulation of the von Bertalanffy growth curve. See methods for more details.

Mortality: Effect of Handling on Tag Retention

Of the 93 shell released in Exmouth Gulf in July 1998, 92 were found 1 mo later in August 1999. From these 92 shell, 2 were dead, 3 had damaged tags and 1 shell had lost both tags. Therefore, total mortality from experimental handling was $2/92 = 2.17\%$, and tag loss was 4.3%.

Mortality: Tagging Estimates

Of the 200 oysters placed-out for 1 y in August 1999, 195 were retrieved live in August 2000, 2 were dead and three were not relocated. The collection rate of $195/200$ (97.5%) indicates that adult mortality was low (2.5% p.a.). Thus, overall direct estimates of annual natural mortality of adult pearl shell (6+ years) were 1% to 2%, which equates to M of 0.02.

Mortality: Catch Curve Analysis of Adult Pearl Shell (6+ years)

Natural mortality (M) ranged from 0.18 or 16.5% per year (80 Mile Beach, inshore shallow) to 0.1 (10%) at the Compass Rose deepwater stocks (Fig. 7). Mortality at the Lacepede Islands (0.148) and 80 Mile Beach offshore shallow was intermediate between these. This trend is correlated with depth (i.e., highest mortality in shallower waters and lowest in deep in the 80 Mile Beach stocks).

Recruitment

Separation of 0+ and 1+ age classes of *P. maxima* spat were obtained consistently over 9 y of sampling the 80 Mile Beach stocks (Fig. 6), and 0–34 mm spat are considered 0+ age (5–8 mo), with 35–75 mm considered 1+. This enabled clear temporal trends in spat settlement to be quantified (Fig. 8), particularly in the Lacepede Islands (Fig. 8). However, the magnitude of the recruitment index differed between research and industry data collection, particularly for the 0+ age class (Fig. 9). Despite this, there was still a significant positive correlation between industry and research personnel data for the 0+ age class ($n = 4$; $r = 0.95$; $P < 0.05$). For the 1+ age class, there was also a positive correlation between industry and research personnel data ($n = 4$; $r = 0.67$; $P > 0.05$), however it was not significant, mainly because of the small sample size (Fig. 8).

Predicting Future Stock Abundance with Recruitment Data

In Zone 2, there was a high positive correlation between 0+ spat abundance and 1+ spat abundance 1 y later for the industry data ($n = 4$; $r = 0.89$), and the research data ($n = 3$; $r = 0.92$). Neither was statistically significant because of the small sample sizes, however they are sufficiently high to enable reasonable confidence in their predictive potential, which needs to be confirmed with more years of sampling.

Sex Ratio

Sex-ratio data confirms that *P. maxima* is a protandrous hermaphrodite (Fig. 10). Size-at-maturity for males was around 110 mm, females were identified from 135 mm onwards and the sex ratio reached 50:50 female to male at approximately 170 mm DVM. From 170–200 mm there was a greater proportion of females in the population (Fig. 10).

DISCUSSION

Results of this study establish for the first time, the crucial demographic parameters of growth, mortality, recruitment and

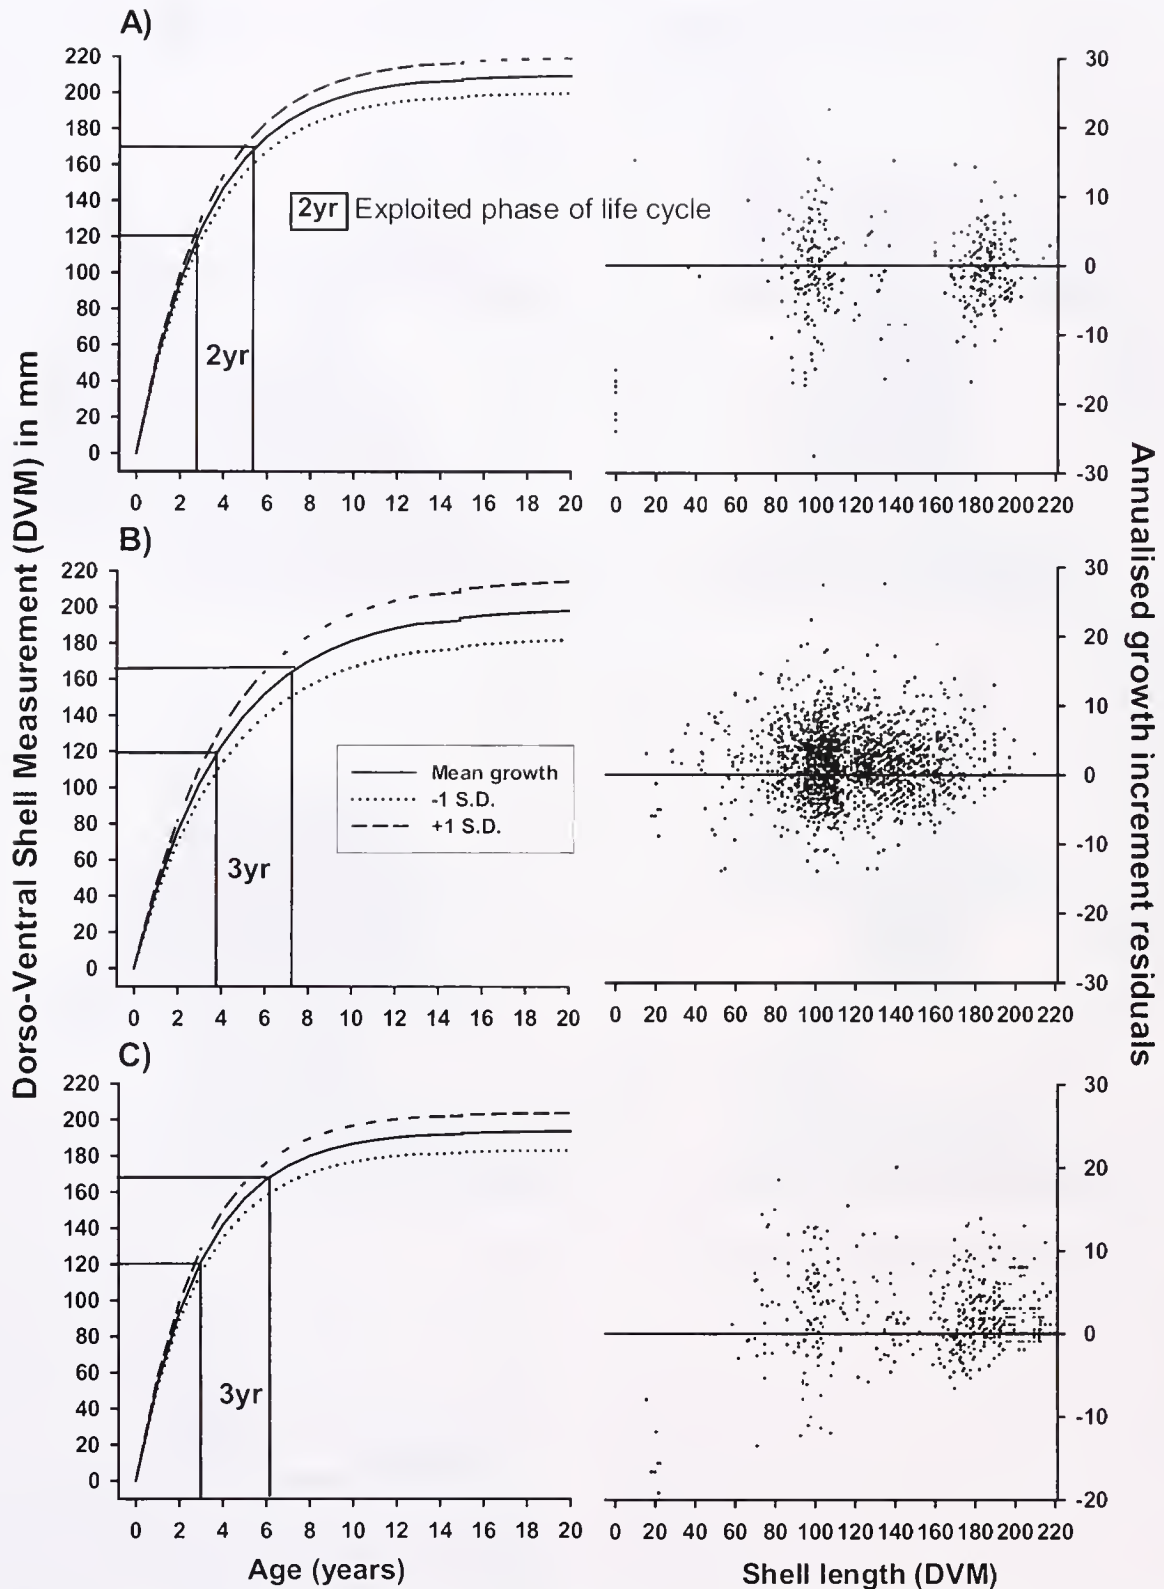

Figure 4. von Bertalanffy growth curves for each population of *Pinctada maxima* (A) Lacepede Islands; (B) 80 Mile Beach; (C) Exmouth Gulf) and annualized growth increment residuals. The exploited phase of the life cycle in each population is also shown.

sex-ratio of wild stocks of *P. maxima* in Western Australia. Growth was estimated *in-situ* for the 3 main commercially fished stocks, the Lacepede Islands, 80 Mile Beach, and Exmouth Gulf stocks, and represent the first published results for *in-situ* assess-

ment of growth of wild stocks of *P. maxima*. This is in contrast to farmed stocks of *P. maxima*, where there have been many assessments of growth, beginning with Wada (1953). Our growth results confirm that the wild fishery in Western Australia is a gauntlet

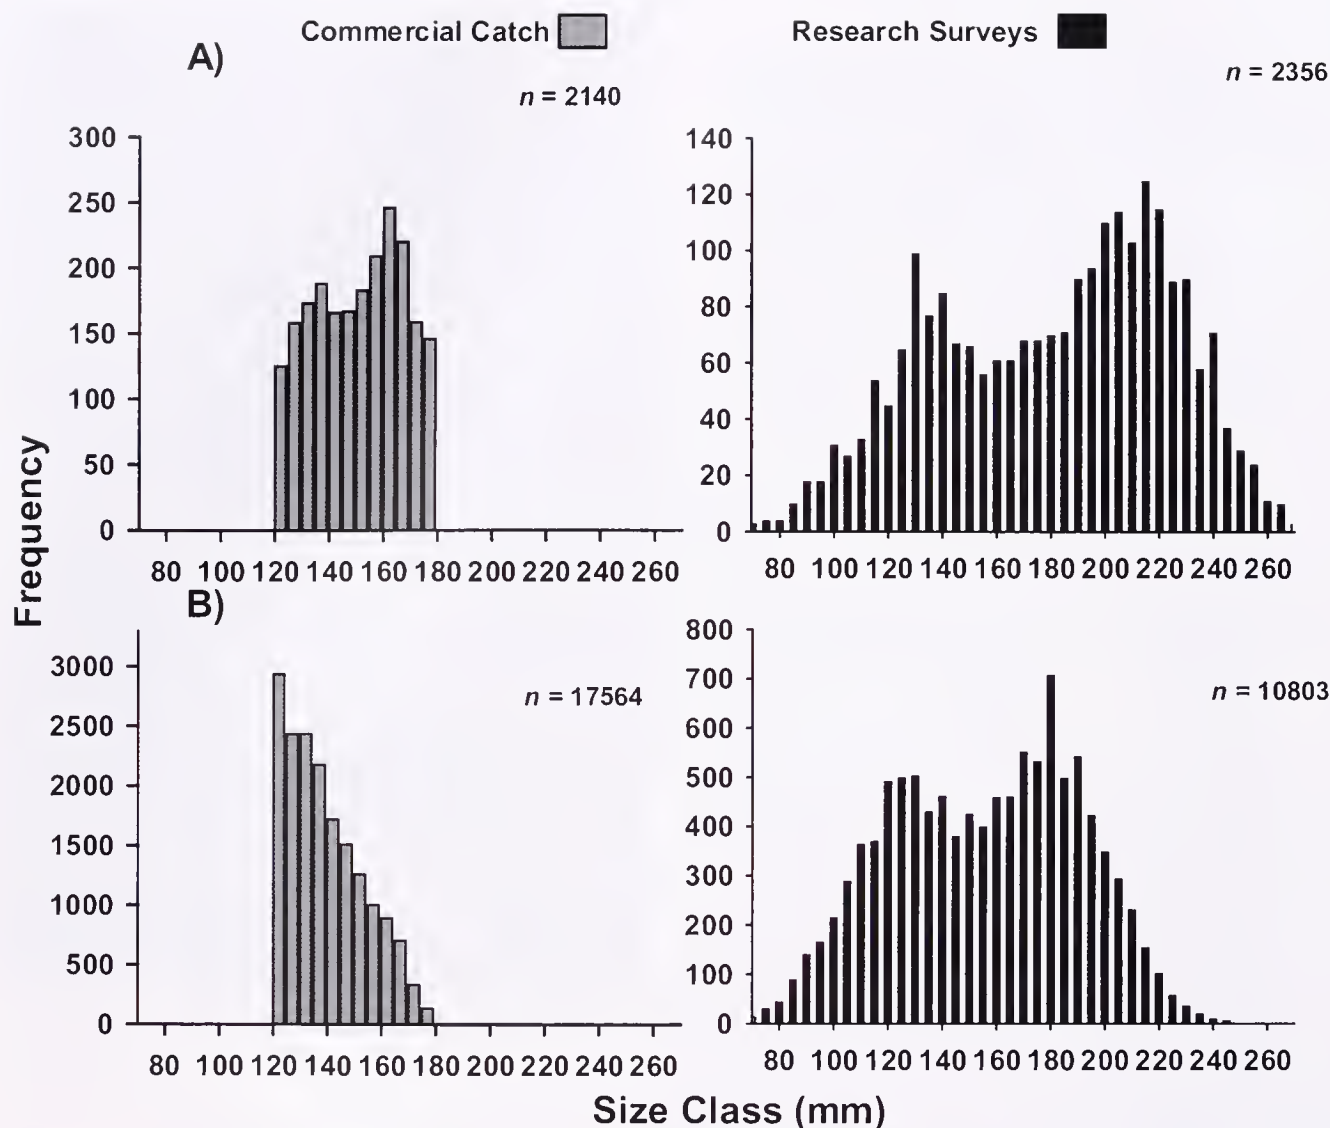

Figure 5. Size-frequency of *Pinctada maxima* found (A) Lacepede Islands (Zone 3) and (B) 80 Mile Beach (Zone 2). Commercial catch data and research survey data are both shown. The two modal peaks in the research survey data are not age classes but result from selective fishing.

fishery, targeting between 2 and 3 age classes, depending on location, and that average growth in the initial years from 0 + to 1 + is relatively slow, at around 30 mm per year, although it can vary considerably between years. A secondary spawning peak of *P. maxima* in March to April (Rose et al. 1990) may affect the integrity of the 1 + cohort data to some degree, however there is enough consistency between years in spat size frequency to be confident that 30 mm per year is an accurate average for 20–40 mm *P. maxima* spat on the 80 Mile Beach. This is slower than growth rates achieved by *P. maxima* spat grown near the surface on long lines, which generally achieve an average increment of 50 mm per year in their first 2 years at farms in the Northwest and North of Australia (D. Mills, pers. comm.). Cooler temperatures and surface boundary effects creating slower flow rates are hypothesized to be the main causes of slower growth in spat from 80 Mile beach stocks. Rose et al. (1990) recorded winter water temperatures dipping to 20°C, which is close to the calculated temperature of 0 growth (18°C) in *P. maxima* (Mills 2000, Pass et al. 1987). Also, spat were collected from wild adult oysters living in

benthic habitats where friction effects naturally slow the average water movement, in comparison with cultured spat that are positioned individually on surface long lines. This practice provides optimal, rather than normal, conditions for growth. Other studies of tropical bivalves also confirm the growth enhancing effect of surface long lines; for example Hart et al. (1999) showed that juvenile growth of a giant clam (*Tridacnidae*) (0–2 y) was considerably improved on surface long lines.

Rose et al. (1990) reported that males in the wild mature at 1 y with a shell height of 110 mm, however our growth results indicate this is incorrect. At 110 mm DVM, the size when males start to mature, their age would be 2 y, and most would be in their third year of life, at least on the 80 Mile Beach stocks. Females do not mature until 4 or 5 y of age at 140 mm DVM. These results show clearly, for the first time, that growth in wild stocks of *P. maxima* is less than that achieved on farms.

In Western Australia, unfished shells grow into the "Mother-of-Pearl" or MOP size-class at 170 mm DVM + and remain unexploited at a low natural mortality rate. Estimates of the age of an

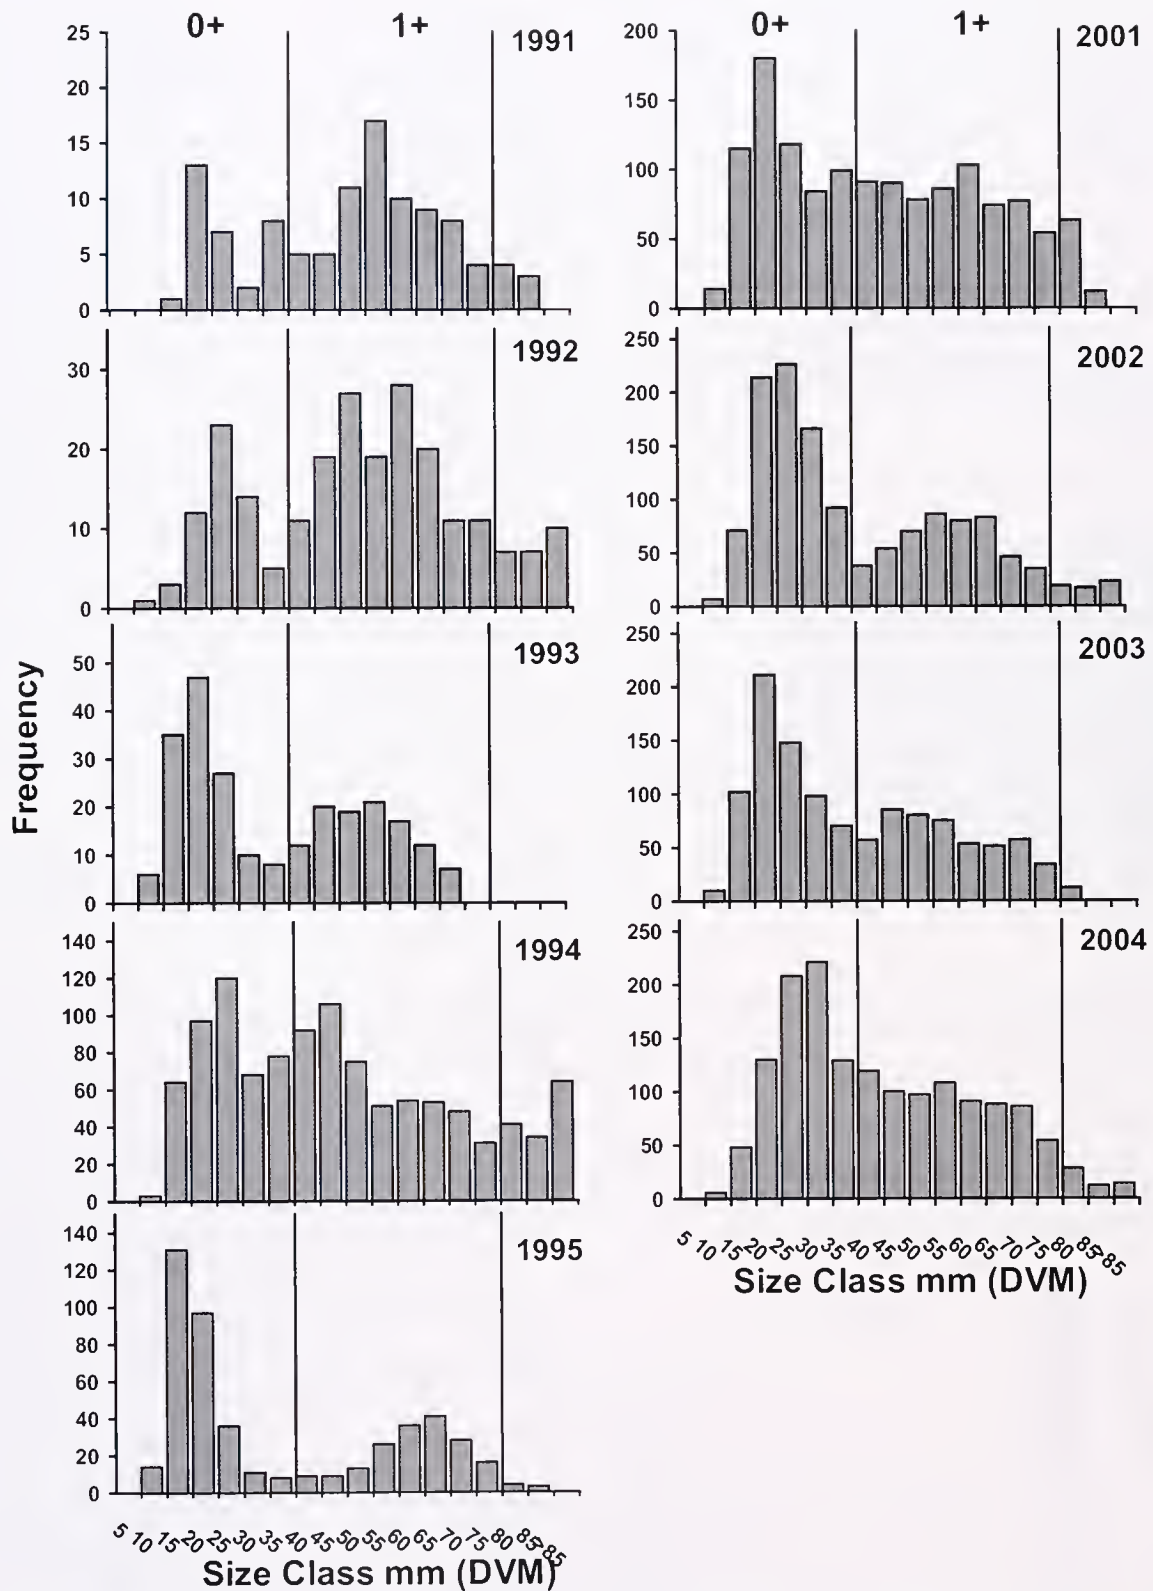

Figure 6. Size frequency of 0 + and 1+ *Pinctada maxima* spat collected from recruitment surveys during the period 1991 to 2004.

exceptionally large oyster found on the 80 Mile Beach fishing grounds (252 mm DVM) are between 15 and 30 y (Hart, unpublished data), hence it is possible that *P. maxima*, which escape commercial exploitation may breed for another 10–15 y. Overall,

Research surveys of MOP have confirmed high abundance of stocks (Hart & Friedman 2004) and preliminary analyses suggest that the balance between recruitment and fishing mortality is generally tipped towards recruitment, except in exceptionally poor

Figure 7. Length converted catch curve analysis for *Pinctada maxima* sampled at 4 populations. (A) 80 Mile inshore shallow; (B) 80 Mile - Offshore shallow; (C) Compass Rose; (D) Lacepede Islands. M = natural mortality.

recruitment years. Stock surveys however, should be carried out every 5 y to measure any change of the breeding stock.

Comparative estimates of the demographic parameters K and L_{∞} for pearl oysters are sparse in literature, owing presumably to

the fact that pearl fisheries were among the earliest marine animals exploited commercially, most of which occurred prior to the development of modern, quantitative biological methods. Saucedo et al. (1998) for example, reports that the natural pearl beds of *Pinctada mazatlanica* in Mexico were subject to 400 y of uncontrolled exploitation, leading to virtual extinction by 1939. Herdman (1903) reports on the great antiquity of the Ceylon pearl oyster fishery, which targeted *Pinctada imbricata* and details individual yearly catches and revenues of this fishery throughout the 1800s at a very fine spatial scale, including an assessment of normal and stunted growth in the presence of overcrowding, however this was before von Bertalanffy's (1938) seminal work. Sims (1992) study on the black-lip pearl oyster (*Pinctada margaritifera*) in the Cook Islands yielded an L_{∞} infinity of 183 mm, and K of 0.26, which is slightly smaller and slower growing than *P. maxima*. This is to be expected because *P. maxima* is recognized as the largest of all pearl oysters in the world (Shirai 1994), although Saucedo et al. (1998) presented data on individual *P. mazatlanica* growing to 190 mm DVM. Considerable spatial and individual variation in growth of *P. maxima* in Western Australia was noted, with a standard deviation of 16 mm from the Zone 2 stocks, and exceptional individuals have been observed as large as 300 mm from the Lacepede Islands. This is confirmed by Wada (1953), who reports that a 300 mm specimen was not uncommon in some fishing areas along the north of Australia and Arafura Sea.

Natural mortality (M) of 170 mm + oysters appeared to be

Figure 8. Trends in abundance of 0+ and 1+ spat of *Pinctada maxima* in Zone 3 (Lacepede Islands) from 2001–2004.

Figure 9. Trends in abundance of 0+ and 1+ spat of *Pinctada maxima* in Zone 2 from 2001 to 2004 (Research and industry data).

location specific, and generally low, with indirect estimates from length-converted catch-curve analysis (0.11–0.18) being higher than direct estimates from tag-recapture studies (0.02). Sims (1992) estimated natural mortality at 0.11 for *Pinctada margaritifera*, which suggests that low rates of M for pearl oysters are to be expected. The differences between M was primarily related to depth, and shallow areas of the pearl stocks may exhibit a higher rate of natural mortality caused by increased turbidity and greater water movement and susceptibility to annual extreme storm events, such as cyclones and perhaps higher predation. We hypothesize that *P. maxima* in Western Australia, a sedentary species having evolved under the influence of huge tides and cyclones would be favored by having low natural mortality as a life-history strategy, indicating a robustness to cope with extreme environmental conditions.

Historically, varying catch per unit effort (CPUE in shells caught per diver hour) in the pearl oyster fishery (Fig. 11), suggests that recruitment is quite variable, a conclusion in common with many marine invertebrate species. Whereas the introduction of GPS (Global Positioning System) in 1994 might have confounded the changes in CPUE occurring at that time, subsequent changes in CPUE suggest that fishery performance can reflect recruitment variation. Understanding this natural variation in recruitment will greatly enhance our management capability of this fishery, and our preliminary work on using the "piggyback" spat recruitment index has yielded promising results. Firstly, it was possible to collect adequate samples of newly settled spat as part of the on-board vessel monitoring program and

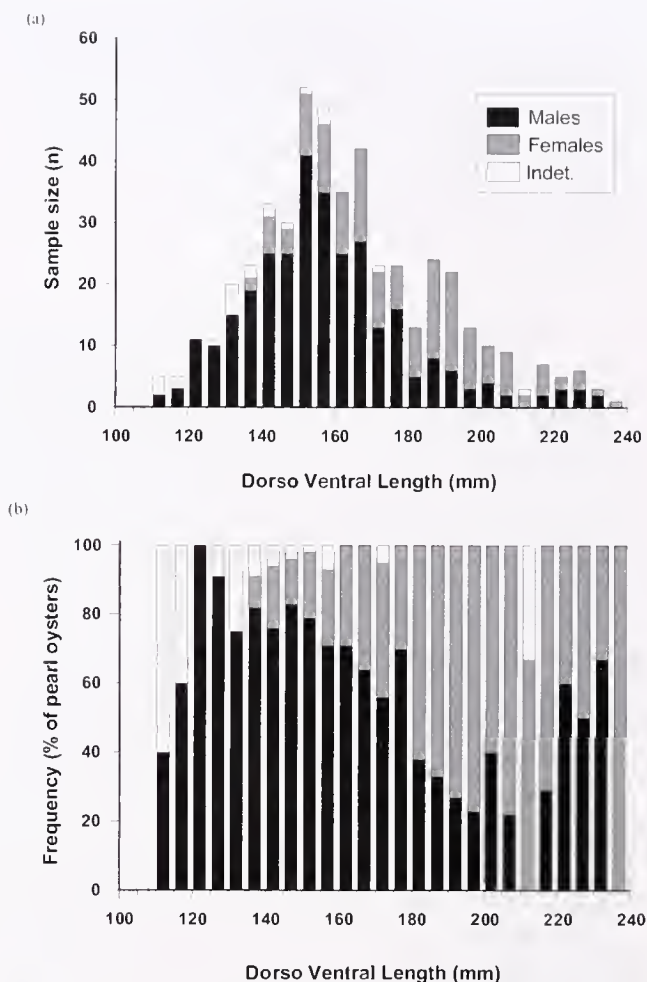

Figure 10. Sex-ratio by size in wild stocks of *Pinctada maxima* from 80 Mile Beach (Zone 2). (a) sample size per size-increment; (b) % frequency by size-increment.

divide them up into two age classes (0+ and 1+). The results proved consistent from year to year because the fishery largely operates within the same 3 mo each year (mid-March to mid-June). Secondly, preliminary predictions detected a future temporal vari-

Figure 11. Catch rate (shells caught per diver hour) in the Western Australian *Pinctada maxima* fishery (Zones 2 and 3 combined) between 1979 and 2004.

ability in CPUE, which is consistent with the past history of CPUE in the fishery, namely that the general pattern has been 2–4 y of “baseline” CPUE around 30 shells per hour, followed by 2–3 y of increased CPUE, up to 60% above the baseline and then a drop back to normal levels. Future work will quantify effects of habitat and depth and other environmental factors, such as variables representing larger oceanographic conditions (e.g., ENSO phenomena) and provide a formal predictive index to assist in managing level of catch.

ACKNOWLEDGMENTS

The authors thank Arrow Pearls, Broome Pearls and Paspaley Pearls Pty Ltd for use of their vessels and divers to conduct the various sampling regimes. Craig Skepper, Clinton Syers, Frank Fabris, Kim Friedman, Dave Murphy, Rod Pearn and Jamie Colquhoun participated in the field sampling and took the photographs. IN PURSUIT OF COST-EFFECTIVE FISHERIES ENHANCEMENT OF NEW SOUTH WALES BLACKLIP ABALONE, *HALIOTIS RUBRA* (LEACH) FISHERY

M. P. HEASMAN*

NSW Department of Primary Industries, Port Stephens Fisheries Centre, Private Bag 1,
Nelson Bay NSW 2315, Australia

ABSTRACT The diverse and often complex essential components of successful marine stock enhancement are briefly reviewed. Progress on a project to enhance the New South Wales blacklip abalone (*Haliotis rubra*) fishery is discussed to demonstrate that for sedentary reef invertebrates such as abalone, successful enhancement entails an understanding of recruitment and production limiting factors. These include age and size specific growth and mortality rates. These variables encompass the influence of other species within reef ecosystems, especially predators and species that compete directly with them for space, shelter and food. This discussion is also used to demonstrate that such difficult projects can be facilitated and refined using a simple bio-economic model centered on two interdependent tasks. The first is to minimize net costs per unit of additional sustainable production generated by enhancement. The second is to determine the minimum amount of additional sustainable production required to render a project cost-effective. This first task has, as expected, proven complex and its resolution protracted and expensive, requiring innovative biotechnology and a comprehensive knowledge of the natural biology of blacklip abalone. This discussion principally reflects the perspective of the direct potential beneficiaries of abalone fisheries enhancement, namely commercial and recreational fishers and does not deal extensively with wider views and interests of other stakeholders, namely relevant government agencies and NGOs and the general public.

KEY WORDS: fisheries enhancement, abalone, *Haliotis rubra*

INTRODUCTION

Generalized Theory and Practice of Marine Fisheries Enhancement

Blankenship and Leber (1997) identified 10 key components as essential for responsible marine stock enhancement. These included the need to: (1) prioritize and select target species for enhancement; (2) develop a species management plan that identifies harvest opportunity, stock rebuilding goals and genetic objectives; (3) define quantitative measures of success; (4) use genetic resource management to avoid deleterious genetic effects; (5) use disease and health management; (6) consider ecological, biological and life-history patterns when forming enhancement objectives and tactics; (7) identify released hatchery seed and assess stocking impacts; (8) use an empirical process for defining optimum release strategies; (9) identify economic and policy guidelines and (10) use adaptive management. Blankenship and Leber (1997) reviewed three finfish case studies to verify that this responsible approach to marine stock management is practical.

In a recent review of the 100 y history of fisheries stock enhancement projects, Molony et al. (2003) concluded that most have had little or no demonstrated success. They ascribe this to undue preoccupation with seed production technology and failure to identify and/or control underlying reasons why the targeted fisheries were underperforming or not meeting management objectives. They also concluded that stock enhancement has often been applied in isolation from other fisheries management tools and have ignored broader ecosystem perspectives. To address these shortcomings, the authors proposed a flow-chart implementation model comprising four sequential steps: (1) review all relevant ecological and stock status management fisheries information; (2) make a comparative evaluation of all relevant fisheries management tools with a potential to meet targeted objectives; (3)

instigate a scientifically based pilot enhancement program with clear appropriately targeted objectives and (4) if warranted by outcomes of the pilot program, initiate a follow-up full scale commercial program.

What follows is a discussion of a research project that has attempted to achieve sustainable and cost-effective enhancement the blacklip abalone (*Haliotis rubra*, Leach) fishery in New South Wales (NSW), using hatchery-produced seed. This research, much of which is reported in more detail by Heasman et al. (2004) in a contract research report, has collectively addressed most of the important issues and elements identified by Blankenship and Leber (1997). Its implementation over a 3-y period generally conformed to the first three sequential steps prescribed by Molony et al. (2003). Towards the end of the third year of pilot seeding operations (step 3), an extensive reappraisal of the project was made. This comprised a repeat of steps 1 and 2 (review of all other relevant fisheries biology and management information) and incorporated a wealth of practical experience gained, together with findings of an extensive array of complementary laboratory and field-based larval and juvenile seeding experiments. It also culminated in the development of bioeconomic benefit and cost and risk assessment model.

Previous Attempts to Enhance Wild Stocks of Abalone With Hatchery-Produced Seed

The efficacy of enhancing wild stocks of abalone with hatchery-produced seed has been investigated internationally and within Australia. As stated by Shepherd et al. (2000), "Release of larvae and juveniles has often been proposed as a panacea for rehabilitating depleted or over exploited reef." Seeding of juveniles has been practiced in Japan for several decades with some success (Kojima 1995, Masuda & Tsukamoto 1998). Larval release has been practiced sporadically in Mexico since the 1960s (Ortiz-Quintanilla 1980). Prior to this study, research in NSW into the efficacy of previously developed techniques for the release of seed abalone was limited to larval releases in Twofold Bay by a company Abalone Shellfish Enterprises Pty Ltd. (Keesing et al. 1994).

*Corresponding author. E-mail: mheasman@bigpond.net.au

Note: these budgets incorporate new highly efficient hatchery and nursery technologies developed in this study but do not include depreciation on plant and equipment.

Although survival of the larvae was not monitored, a localized high density aggregation of sublegal size abalone was observed at one release site several years later (Ross Werner, pers. comm. 1998). This information, though anecdotal, encouraged collaborative involvement of total allowable commercial catch (TACC) quota holders in this project as mediated through the NSW abalone management and advisory committee (ABMAC).

Larvae of *H. rubra* and greenlip abalone (*Haliotis laevigata*, Donovan) were released at different densities in South Australia by Preece et al. (1997). Generally low and strongly density-dependent survival in the range 0.02% to 7.8%, occurred 6–7 d after settlement. Such strongly density-dependent rates of mortality of larvae and early postlarvae were also reported by McShane (1991) in relation to naturally recruited stocks of *H. rubra* in north eastern Victoria. On the basis of these reports, Shepherd et al. (2000) recommended against larval seeding, as did Schiel (1993), based on similar results with seeding of *H. iris* (Paua) larvae in New Zealand.

In a review of experimental releases of 7-mo-old (12 mm) hatchery-produced *H. rubra* in Tasmania, Shepherd et al. (2000) concluded that very high rates of mortality over the first few weeks were due mainly to handling stress. They also concluded that high mortality up to 1 y after release was caused by persistent density-dependent mortality factors and predator naivety.

Status of the NSW Abalone Fishery and Scope for Enhancement

The NSW abalone fishery is based entirely on *H. rubra* and is largely confined to the southern half of the state. Annual catch (Fig. 1) peaked at about 1200 t in 1971/1972, and remained above 600 t through to the early 1980s. Since 1973 a succession of fishery management initiatives (Fig. 1) have been implemented. These have included a reduction in effort through license regulation, limiting catch by quota allocation and introduction of size limitations. Regional fishing closures were also imposed between Port Stephens (32°42'S; 152°10'E) and Jervis Bay (35°03'S; 150°44'E) after a major depletion of stocks by the disease *Perkinsus* between 2000 and 2002. A TACC of 370 t was first introduced in 1989. Subsequently it has been progressively reduced to 333 t in 1996, to 305 t in 2000 and down to its current level of 281 t in 2003 (NSW Fisheries 2004). Subsequently, it was further reduced to 208 t in 2004 and to 130 t in 2005.

Figure 1. Annual commercial catch data and management initiatives for the NSW *H. rubra* fishery since its inception in 1960. (Source data: Anon 2002; NSW Fisheries 2004.).

A common anecdotal report of *H. rubra* fishers over this 30-y period is that many formerly productive areas of reef, typified by foliose algae (seaweed) and associated complex communities of fish and invertebrates including abalone, have undergone a transition to "barrens." These bare rock areas typically carry high densities of the black (=purple) sea urchin, *Centrostephanus rodgersii*, (J. Smythe, pers. comm.). Such observations are compatible with the findings of Andrew and Underwood (1992) that densities of *H. rubra* and *C. rodgersii* are negatively associated and by the finding of Shepherd (1973) that continuous grazing pressure, exerted by dense aggregations of *C. rodgersii*, can degrade complex community reefs. Andrew and O'Neill (2000) and Worthington and Blount (2003) estimate that barrens habitat constitute an average of 40% to 50% of near-shore reef areas in NSW.

Whereas the massive extent of barrens habitat in NSW appears to offer scope for rehabilitation of depleted *H. rubra* stocks, natural recolonization is probably limited by the combination of competitive exclusion by *C. rodgersii* and the very restricted dispersal of *H. rubra* larvae from their parents (Prince et al. 1988). Hamer (1982) and Andrew et al. (1998) demonstrated that habitat improvement by way of culling urchins from urchin dominated reef in Southern NSW resulted in rapid recovery to abalone densities typical of high producing reef within 3–4 y. The recovery process also included a dramatic increase in the coverage and biomass of foliose algae and an associated increase in biodiversity of floral and faunal assemblages. Nevertheless, urchin culling is very labor-intensive and colonization is limited to small localized areas. Accordingly, the task of culling *C. rodgersii* from up to 50% of coastal reefs commercially fished for abalone in NSW, that collectively comprise about 5000 ha, is daunting.

By contrast, mass hatchery production and release of seed *H. rubra* provides a potentially powerful means of rapidly enhancing depleted abalone subpopulations over extensive areas. Seeding also addresses other factors limiting recruitment and consequentially sustainable yields. Such factors include the combined effects of commercial, recreational and illegal fishing pressure and diseases such as *Perkinsus* that has devastated stocks north from Jervis Bay to Port Stephens (Worthington 2002). Other recruitment limiting factors are pollution and competitive exclusion especially of settlement stage larvae and small postlarvae by a diverse array of large common surface grazers. These comprise other gastropods including several ubiquitous turban shell species and a comparable array of urchins additional to *C. rodgersii*. In a recent experiment (Heasman unpublished data) high densities of the common tent shell (*Astraliun tentoriformis*) or of *Turbo torquatus* in high densities were found to reduce yields of 1-wk-old *H. rubra* postlarvae, seeded as larvae onto natural CCA (crustose coralline algae) rock settlement substrates, by 98% and 94% respectively. In the same experiment, the presence of either black urchins (*C. rodgersii*) or adult abalone reduced postlarval yields by similarly high margins of 90% and 78% respectively.

SEED PRODUCTION AND DEPLOYMENT TECHNOLOGY

Improved Year-round Availability of Ripe Broodstock for Induced Spawning and Hatchery Production

Attempts to immediately produce viable eggs from wild-caught adults were unsuccessful, with a significant number of viable eggs (1.5 million) being produced on only 1 of 42 occasions. Over the same period seven successful inductions of spawning were

achieved using broodstock acclimatized over longer periods in ambient flow-through seawater tanks. These yielded 26.8 million eggs (mean fecundity 1.12 million eggs/spawner) that in turn yielded 13.3 million competent larvae. However, these spawnings and subsequent hatchery operations occurred at irregular intervals and were largely limited to the spring to early summer natural breeding season of *H. rubra* in NSW.

For the first time in Australia, greatly improved access to ripe, ready-to-spawn broodstock was achieved with captive stock conditioned in a recirculating seawater system operated at $15 \pm 2^\circ\text{C}$. These stock were originally collected from seven localities between Port Stephens, 150 km north of Sydney, to Disaster Bay ($37^\circ 15'$; $149^\circ 58'E$) near the Victorian border. Half (17) of 34 spawning induction operations, spread throughout the year, were successful and yielded 59.3 million eggs. Mean spawning response rate using these conditioned broodstock was 11% (85 out of 785 females). Mean fecundity (\pm s.e.) was 1.25 ± 0.49 million eggs/spawner (range of 42,000–4.0 million). A total of 24.0 million competent larvae were produced and used for larval seeding experiments or for nursery production of juvenile seed and related experiments. Yields of 7–8-d-old competent larvae from eggs averaged 40% (range 8% to 71%), which was consistent with rates

routinely reported by commercial hatcheries in Australia. Subsequent yields of 6–9 mo old juvenile seed from competent larvae averaged 5.7% and varied greatly from 8% to 75%.

Hatchery and Nursery Technology Development

The low and inconsistent yields of juveniles raised the need for better knowledge of and control over nursery production. A mean shell length of about 1.5 mm was identified as the minimum size needed to ensure trouble free weaning of postlarvae onto finely ground particulate diets (Adam and Amos P/L, South Australia). Postlarvae grew at an exponential rate regardless of season or seed density (Fig. 2). Plate residence time from settlement to 1,500 μm ranged widely. Batches reared in summer/early autumn required only 30–35 d. At the other extreme, winter and early spring reared batches required 50–72 d. Growth rates thus appeared primarily dependent on seasonal temperature.

An important feature of growth on diatom plates is that it continues exponentially until either food runs out (plates grazed out), in which case it abruptly stops, or when postlarvae reach a mean shell length of 1–2 mm at which time they can be successfully transferred to raceways for weaning onto artificial diets. As

Batch	Larval seeding density	Spawning Date	Growth season	Period to min. mean weaning size of 1500 microns	Mean growth rate microns/day	Best fit regression	R ²

H	2507/plate	1/02/00	late Summer	35 days	33 $\mu\text{m/day}$	$y = 337.31e^{0.0431x}$	0.9923

Figure 2. Variation in growth of eight commercial scale batches of *H. rubra* postlarvae grown on conventional diatom plates. Note: growth was exponential in all cases (Heasman et al. 2004).

illustrated in Figure 3, production batches that were inadvertently allowed to exhaust diatom films after having reached the minimum weaning size, stopped growing and starved before being harvested from nursery plates. Substantial and sometimes catastrophic losses of postlarvae occurred as a consequence of such episodes. This was probably caused by combined stresses of starvation, anesthesia and handling when harvested and transferred to shallow exposed raceway habitats for weaning. The size and age at which growth stopped and starvation began appeared inversely related to initial density of competent larvae seeded onto the plates.

Results of Experiments Conducted to Improve the Reliability and Cost Efficiency of Large-Scale Production of Juvenile *H. rubra* Seed

Results of one experiment to investigate effects of variable larval density of 500–4,000 larvae per plate ($0.15\text{--}1.2\text{ cm}^{-2}$) on settlement, metamorphosis and subsequent growth on conventional nursery plates showed that yields of postlarvae (Fig. 4) peaked after 4–7 d. They also showed that yields increased from 26% to 71% with increasing seeding density. However, from day 7–28 after seeding, survival across all seeding densities progressively converged to a common rate of about 20% that persisted until the termination of the experiment at day 56. Growth (Fig. 5) remained independent of initial seeding density up to 14 d, averaging about $14\text{ }\mu\text{m}$ per day. Subsequent growth became progressively more density dependent. By day 56, growth rates at residual densities of 10, 100 and 1,000 postlarvae per plate averaged about 40, 30 and $22\text{ }\mu\text{m/day}$ respectively. Minimum mean shell lengths of about $1,400\text{ }\mu\text{m}$ at day 56, attained at the highest initial density of 4,000 postlarvae per plate, were nevertheless found to be acceptable for the purpose of early weaning of postlarvae. These improved techniques provide scope to increase output per plate from one to at least four batches per year and to increase yield densities to a consistent range of up to 500–1,000/plate, thereby greatly raising annual yield/plate/year up from 30–80 up to a range of 2,000–4,000.

In another experiment, effects of temperature on settlement, metamorphosis and early postsettlement growth and survival were investigated. Settlement rates on natural CCA coated rock settlement substrates ranged from 20% to 40%. Peak settlement and

Figure 3. Effect of over-grazing on growth of *H. rubra* postlarvae seeded onto conventional diatom plates (Heasman et al. 2004). Note: initial exponential growth (solid circles) succeeded by stalled growth and starvation (open circles). Bars are \pm SE of means, $n = 30$.

yields of postlarvae occurred at about 17°C (Fig. 6). During the first week after settlement growth rates of postlarvae (Fig. 7) increased progressively from zero at 10°C to a peak of $\sim 30\text{ }\mu\text{m/day}$ at 23°C , but then fell dramatically back to zero with a further rise in temperature to 27°C . Effects of temperature on growth of four juvenile age/size classes of *H. rubra* (Fig. 8 a to d) showed that further downward shift in optimum temperature from about 17°C to 15°C occurs with progressive age and size in juvenile *H. rubra*. Results also demonstrated that moderate to high rates of settlement and subsequent growth and survival could be achieved year-round on the central coast of NSW at mean monthly sea temperatures in the range 16°C to 22°C but that successful year-round hatchery-ambient temperature nursery production would be limited at more southern sites subject to sea temperatures below about 14°C .

Figure 6. Effect of temperature on yield of day 6 *H. rubra* postlarvae as a percentage of larvae seeded onto crustose coralline algae coated rocks (Heasman et al. 2004).

Transportation and Storage of Juvenile *H. rubra*

The need to transport and deploy batches of up to several hundred thousand 6–9-mo-old (5–15 mm) juvenile *H. rubra* up to 500 km from the hatchery prompted the development of suitable storage and transportation methods. Key issues addressed were whether stock should be stored and transported wet or damp, optimum temperatures for storage and transportation and the maximum duration over which they can be safely stored and/or transported without compromising the postrelease vigor and survival. Juvenile *H. rubra* (mean SL, 14 mm) previously held at ambient temperatures of 18°C to 22°C survived at acceptable rates (i.e., above 80%) for up to 48 h when stored damp in pure oxygen between 13°C and 16°C. The best 48 h survival rate of 95% was achieved with damp storage at 14°C. Generally poorer rates achieved with wet transportation were ascribed to declining physiochemical conditions, especially dissolved oxygen that rapidly fell below an acceptable threshold of 95% saturation.

Figure 7. Effect of temperature on growth of day 6 *H. rubra* postlarvae seeded onto crustose coralline coated rocks (Heasman et al. 2004).

Field Deployment and Postrelease Growth and Survival

Improved methods of seeding hatchery-produced *H. rubra* larvae and juveniles onto natural reefs were developed, and the effectiveness of these methods to deliver competent larvae and juveniles to reefs tested. Several alternative methods of monitoring the settlement and early survival of larvae, postlarvae and juveniles within their respective release areas were developed. Field experiments were used to demonstrate the ability of juveniles to rapidly disperse from points of release and provided greater insight into factors that must be considered when attempting to estimate long-term survival of seeded stock.

In excess of 24 million larvae and nearly 900,000 juvenile *H. rubra*, most falling within the "button" mean size range of 6–18 mm SL, were seeded to 57 sites within six locations along the NSW coast. The survival and growth of larvae and juveniles were monitored for periods up to 30 mo. Short-term (<2 mo) sampling was used to investigate movement of juveniles and to compare alternative sampling techniques. The best survival for seeded larvae a year or more after release was 125 out of 1.1 million (1 in 8,800) recorded 553 days after release. As in earlier abalone seeding studies (Preece et al. 1997) seeding of ready-to-settle larvae was shown here to be fraught with practical difficulties and with very low rates of survival projected to yield less than 1 in 20,000 to a legal shell length of 115 mm.

Juveniles were mainly deployed as clusters of 700–2,500 in predator protective release devices initially comprising CCA coated rocks within wire mesh cylinders. These were superseded by rectangular boxes comprising sections of PVC down-pipe. Mean survival rates 1–2 y after release ranged from 0% to 4%. Average growth rates were similar among and between sites with juveniles expected to reach maturity (>90 mm SL) after 2.5–3.5 y, and projected to reach legal SL of 115 mm after 4 y. These low survival rates prompted a compilation and analysis of published age and size-specific mortality data for *H. rubra* (Table 1, Fig. 9) that were used to estimate yield per recruit and related parameters for a wide range of age/size classes of seed from competent larvae to 6-y-old adults (Table 2). A review of published ecological information on *H. rubra* revealed that, although 1–4-wk-old wild postlarvae occur at natural densities of up to several 1000/m², and 6-mo-old juveniles at up to 30/m², survivors of these groups converged to a common narrow density range of 1–3/m² as 15–30 mm, 1+ year olds (Prince et al. 1988, McShane 1991, Shepherd et al. 2000). It was then postulated that if natural survival rates of 6–9-mo-old button size (7–15 mm) juveniles, through to the minimum legal size, of 1 in 20–30 are to be achieved with hatchery-produced seed, then such seed should be sparsely deployed at densities matched to the food based carrying capacity of CCA rock habitats of this size/age class of juveniles, rather than in large dense clusters as previously practiced.

Evaluation of Postlarvae as an Alternative to Competent Larvae for Seeding

Major practical advantages of using week old postlarvae rather than settlement stage larvae for seeding operations were also identified in three laboratory experiments. Results (Fig. 10) showed that postlarvae can be readily seeded at very high densities onto small CCA coated pebbles (vector rocks) and retained for up to 8 d without significant restriction of growth or ability to rapidly disperse into simulated small boulder habitats after release. Carrying capacity of CCA rock habitat declines reciprocally with exponential increases in the biomass of individual *H. rubra*, falling to

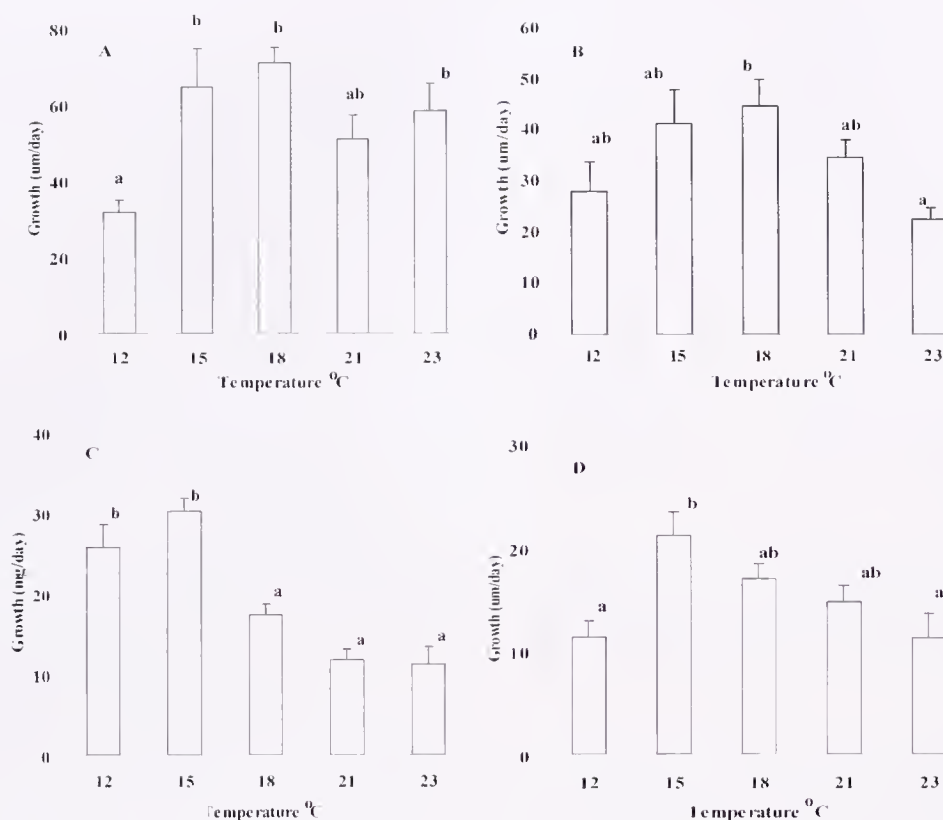

Figure 8. Effect of temperature on growth (a) in shell length of 3 mo old, 2–6 mm; (b) in shell length of 7 mo old, 6–8 mm; (c) in biomass of 17 mo old, 20–25 mm and (d) in shell length of 30 mo old, 50–60 mm, juvenile *H. rubra*. Bars are \pm SE, $n = 4$ (Heasman et al. 2004).

densities levels of 1,000–2,000/m² for 2-mo-old (1.5 mm) postlarvae (Fig. 11), and by extrapolation, to levels of around ≤ 30 /m² for 6-mo-old (7 mm) juveniles. The latter was consistent with above cited peak densities reported for equivalent wild *H. rubra*. Surface grazing on CCA thallus and associated epibiota remains the primary food source of juveniles up to at least 10 mm SL and is only then progressively supplanted by drift seaweed over the following

1–2 y in individuals up to at least 35 mm SL (Shepherd & Daume 1996). An important aspect of these findings is that they were consistent with the earlier-cited convergence of 1+-y-old wild juveniles to densities of 1–3/m². These observed carrying capacity limitations of CCA rock habitats occurred in the absence of other important density and survival limiting factors, namely competition from other surface grazers such as urchins and other gastro-

TABLE 1.

Published age related mortality data for wild *Haliotis rubra* (See Shepherd & Breen 1992, for the mathematical relationship between instantaneous and proportional mortality).

Mean Age (Age Span)	Survival for Period or Per Year	M (Annualized Instantaneous Natural Rate of Mortality)	Source
25 days (0–49 days)	0.5%	311/y	Preece et al. 1997
80 days (1 week to 5 months)	3%	6.6–10.2 (8.4)/y	McShane 1991
4 months (1 week to 8 months)	5.5%	1.4/y	Prince et al. 1988

2 years (1.5–2.5 years)	44% per year	0.81/y	Day & Leorke 1986
2.25 years (2 to 2.5 years)	41% per year	0.9/y	Prince et al. 1988
2.5 years (2 to 3 years)	64% per year	0.45/y	Hamer 1982 (Botany Bay stock)
3 years (2–4 years)	66% per year	0.42/y	Shepherd & Breen 1992
3.3 years (3 to 3.5 years)	45% per year	0.8/y	Prince et al. 1988
3.5 years (2–5 years)	70% per year	0.36/y	Shepherd et al. 1982
4 years (2–6 years)	81% per year	0.21/y	Shepherd et al. 1982
4.3 years (4 to 4.5 years)	74% per year	0.3/y	Prince et al. 1988
4.5 years (4 to 5 years)	76% per year	0.274/y	Hamer 1982 (Eden Stock)
5+ years	82% per year	0.20/y	Beinssen & Powell 1979
5.3 years (5 to 5.5 years)	90% per year	0.1/y	Prince et al. 1988
6.3 years (6 to 6.5 years)	78% per year	0.25/y	Prince et al. 1988

Figure 9. Age related annualized instantaneous mortality rates for wild *H. rubra* (see Table 1 for source of data).

pods and predation especially by finfish especially wrasses (Shepherd & Turner 1985, Shepherd 1998), wirra cod (*Acanthistius ocellatus*) and morwong (*Cheilodactylus fuscus*) (Heasman, unpublished observations) and large invertebrates including starfish, rock lobsters, large crabs and octopus (Shepherd & Breen 1992, Shepherd 1998). Accordingly, the carrying capacity of CCA rock habitats can be largely ascribed to nutritional factors in juveniles up to 10-mm SL and an important but diminishing factor in larger juveniles to 35-mm SL and around 18 mo of age.

On the strength of these findings, a final reef seeding experiment was conducted at Disaster Bay near the NSW/Victorian border. Two deployment treatments; the first consisting of 10 evenly spread clusters of 100 juveniles, averaging 15-mm SL, and the second a central cluster of 1,000 juveniles of the same size, were each deployed over three replicate 113 m² sites. This represented a targeted seeding density of less than 10 juveniles/m², typical for this size/age class of juveniles on healthy productive reef (Prince et al. 1988, McShane 1991, Shepherd et al. 2000). A year later, mean survival across sites seeded with 10 × 100 juveniles was within the expected range for equivalent wild stock, namely 12.5% (range 5% to 23%), whereas that of the alternative clustered treatment was only 3.8% (range 0% to 9%).

DEVELOPMENT OF A BIO-ECONOMIC MODEL FOR ENHANCING THE NSW ABALONE FISHERY

Many of the earlier mentioned findings were used to develop a comparative bio-economic model for *H. rubra* fisheries enhancement using alternative age/size classes of seed. The model is based on the most fundamental of economic equations:

$$\text{Profit} = \text{Revenue} - \text{Total costs}$$

where:

Revenue = long-term average beach price for abalone
× additional sustainable catch generated by seeding

Total costs = costs of all elements of production and deployment of seed but not including those of monitoring the wider environmental consequences of seeding, especially impacts on plant and animal communities and on the genetics of extant wild *H. rubra* populations.

Key inputs, assumptions and rationale thereof associated with this model as follows:

- Additional sustainable annual catch targeted is 300 t (≅ 1 million, 120 mm abalone @ 300 g). This is valued at AUS15M based on an assumed average beach price of AU\$45/kg (AUS15 ea.) (ABARE 2003). The rationale for nominating an enhancement target of an additional 300 t/year, is that it would restore the total commercial catch to a range of 500–600 t/year, which approximates the median annual catch of the fishery since its inception in 1960 (Fig. 1). It is likely that enhanced production of *H. rubra* can only occur at the expense of other reef surface and drift seaweed grazers that compete with *H. rubra* for food and space. However, when it is considered that 300 t of additional *H. rubra* equates to about 0.6% of the biomass of its most important competitor, the black sea urchin, *C. rodgersii*, estimated at 40,000–50,000 t by Worthington and Blount (2003), such impacts are likely to be sustainable.
- The assumed mean age and weight of released abalone at harvest are 5 y and 300 g respectively. This estimate constitutes a median growth rate for *H. rubra* populations throughout NSW, based on regional specific rates originally derived from tag and recapture size data reported by Hamer (1982) and re-evaluated by Worthington and Andrew (1997).
- The five size/age classes of seed (Tables 2–3) and associated assumptions were as follows:
 1. *Competent larvae*. It was assumed that only 1 in about 20,000 seeded larvae would survive to market size adults in compliance with yield per recruit predictions presented in Table 2. The latter, including a mortality rate of ~95% in the first week, are based on published instantaneous mortality data for wild *H. rubra* presented in Figure 9 and assume that seeding does not significantly reduce natural recruitment. Apart from enormous logistical problems of deploying the requisite 20 billion larvae over hundreds of hectares of juvenile habitat by SCUBA under calm sea conditions, the production of the 2 billion larvae required would entail the reproductive conditioning and induced spawning of about 30,000 captive female broodstock (Table 3). The latter is considered impractical if not cost prohibitive.
 2. *0.4-mm postlarvae*. It was assumed that postlarvae would be preseeded onto vector rocks thereby circumventing otherwise prohibitively costly and difficult production and deployment problems plus very high postrelease mortality losses sustained by larvae and postlarvae during the first week in the wild. An assumed yield per recruit rate of 1 harvestable *H. rubra* per 2,000 seeded postlarvae is based on data presented in Table 2 and incorporates an experimentally determined postsettlement mortality rate of 50% in the absence of predators. This particular mode of seeding would require year-round reproductive conditioning and induced spawning of about 3,000 captive female broodstock (Table 3). The latter, although daunting, is considered practicable and affordable. The most critical limitation of this seeding strategy is uncertainty surrounding the fact that it has not been experimentally trialed in the field let alone on a commercially significant scale.
 3. *2-mm postlarvae*. An estimated yield per recruit of 1 harvestable *H. rubra* per 157 ex-diatom nursery plate 2 mm postlarvae is based on reported age specific natural mortality data presented in Table 2. Production of requisite 157 mil-

lion 2-mm postlarvae, needed to raise sustainable fisheries yields by 300 t, would be cost prohibitive using current commercial hatchery technology. Although the scale of such seed production dwarfs that of existing commercial hatcheries in southern Australia, it is nevertheless considered to be practicable and affordable provided much more space, labor and cost efficient hatchery and nursery technologies, developed in this project, are used. Using such technology would entail the reproductive conditioning and induced spawning of 3,200 captive female broodstock. Again, the most critical limitation of this seeding option is uncertainty surrounding the fact that it has not been experimentally trialed in the field let alone on a commercially significant scale.

4. *8-mm juveniles* ("buttons"). An estimated yield per recruit of 1 harvestable *H. rubra* per 26 "buttons" is based on mortality data of wild *H. rubra* data presented in Table 2. Production of the 26 million buttons required would entail the reproductive conditioning and induced spawning of 2,600 captive female broodstock (Table 3). As with the previous two alternative seed classes, this relatively large broodstock requirement is considered both practicable and affordable as is seed production using new high efficiency hatchery and nursery technology developed during this project. However unlike week-old postlarvae and 2-mm postlarvae, commercial-scale low density dispersed seeding methods for this class of seed have been fully developed and very extensively trialed in the field over the past 5 y.
5. *40-mm juveniles*. An estimated yield per recruit of 1 harvestable *H. rubra* per 15 seed comprising 40 mm juveniles, is based of mortality data of wild *H. rubra* data presented in Table 2. Production of the 15 million required juveniles would entail the reproductive conditioning and induced spawning of 2,900 captive female broodstock (Table 3). As with the previous three alternative seed classes, this broodstock requirement, though relatively large is considered both practicable and affordable. The extremely large seed production requirement of 15 million 40 mm juveniles equates to 150 t live weight, which is likely to be cost prohibitive being about twice the annual output of Australia's largest producing farm in 2004/5 (J. Hall, King Island Abalone P/L, pers. comm.). Further factors mitigating against these large seed are daunting logistical difficulties of handling, transporting and dispersion in the field.

Information provided in Table 3 summarizes and compares key logistical, technical and cost issues in producing and deploying the five alternative size/age classes of seed. It also compares utility of producing each size/age class using either conventional single annual batch hatchery production with much more efficient technology developed during this project.

Predictions regarding use of button size juveniles as seed are particularly encouraging in that the potential margin for profit forecast is so handsome that break-even enhancement would still occur even if survival of hatchery-produced seed fell as low as 10% that of wild counterparts. Alternatively, if average survival rates of say 25% to 50% of comparable wild stock are achievable, profitable seeding of depleted populations of abalone could still be attained at much smaller scales of operation than applied to this model, which assumes 100% parity with survival of wild counterparts.

Figure 10. Relationship between residual density and growth of *H. rubra* postlarvae seeded onto natural CCA settlement substrates after 2, 8 and 16 days (Heasman et al. 2004).

The model also predicts that seeding of larvae is likely to be unprofitable and also casts doubt on the economic viability of large-scale seeding of natural reef using advanced (18-mo-old, 40-mm) juvenile *H. rubra*. This is not to say that cost-effective seeding of more advanced juveniles cannot be achieved under reduced competition for food and shelter from competitors and/or reduced predation. For example, R. Day (pers. comm.) reported 50% survival of green lip abalone (*H. laevisgata*) 1 year after being seeded as 28 mm SL juveniles onto reefs constructed from natural reef rocks in shallow, high food flux (drift seaweed) sea-grass beds.

RECENT DEVELOPMENTS

Continuing research of cost-effective technology for enhancing the *H. rubra* fishery in NSW and elsewhere in southern Australia is being pursued under a 12-mo extension of this project. Continuing research towards improving postrelease survival is now being undertaken by A. Underwood and G. Chapman (Sydney University). All field experimentation has been confined to the Port Stephens area because stock translocation limitations imposed by an outbreak of the disease *Perkinsus* that devastated the region's *H. rubra* stocks by an estimated 90% between 2000 and 2002 (Daly 2004). This research is further addressing a number of factors likely to influence postrelease survival that includes evaluation of:

- clustered and dispersed seeding of button size (5–15 mm) juveniles,
- size of juveniles within the button size range on postrelease survival,
- urchin shadows or similar devices for reducing early postrelease mortality,
- multiple low-density seeding of sites and single higher density seeding, and
- natural and artificial diets on postrelease performance of seeded juveniles.

Complementary research being undertaken by NSW Fisheries includes development of a novel method of achieving low density dispersed seeding. This has involved the design and manufacture of small, predator-protective release capsules that accommodate only 10–20 button size seed. These miniaturized deployment devices can be broadcast over entire juvenile habitats of depleted reefs during daylight hours from surface craft, thereby negating costly deployment by divers. A key design feature of the capsules is that they pack together to form complete level platforms. This feature together with the use of intensive light, encourages in excess of 95% of the "buttons" to self-load into the capsules

Figure 11. Residual density of *H. rubra* postlarvae per liter of CCA rock after 56 days. Bars are \pm SE, $n = 4$ (Heasman et al. 2004). Note: 100 postlarvae per liter of CCA rock represents 1000 per m^2 of surface area.

(Heasman, unpublished data). Once loaded, the "buttons" can be maintained within the capsules in good health for several days of storage awaiting either more favorable sea and weather conditions or off-road transportation to sites up to several hundred kilometers from the hatchery. The latest advance in this technology has been the development of two alternative environmentally friendly forms of the capsule. One is manufactured from a specially developed biodegradable resin and the other of aluminum that will corrode away in seawater within a year.

In late July and early August 2005, almost 60,000 button size (average SL 11 mm) juveniles were stocked into aluminum dispersion release devices. Approximately 560 devices containing an average of 17 "buttons" were used to seed each of six 1,000 m² sites marked by surface buoys. All six seeded and an additional six unseeded control sites were located along an 8 km section of coast on the southern side of the Tomaree Peninsula at Port Stephens. All sites were considered typical juvenile habitat comprising a high component of crustose coralline algae coated boulders, immediately adjacent to locations identified by local commercial fishermen to have consistently supported good catches prior to *Perkinsus* epidemics that decimated these stocks between 2000 and 2002. Broadcast seeding of the capsules from a 10-m vessel required only a few minutes per site. Aims of this long term experiment are to evaluate the commercial utility of dispersed

seeding of depleted stocks and to assess genetic impacts of such releases.

Possible deleterious genetic consequences of seeding large numbers of juveniles produced in the hatchery from relatively small number of parents have also been addressed in the current project through the development and assessment of triploid *H. rubra*. Chemical induction techniques yielding almost 100% stable triploids were developed. These triploids were subsequently shown to be reproductively sterile and although no whole weight growth advantage could be demonstrated in triploids up to 37 mo old and 70 mm SL, yield of saleable flesh was 20% greater than in full sib diploids (Lui 2005). Furthermore, one particular treatment used to induce triploidy was found to have inadvertently produced significant numbers of tetraploid individuals paving the way for future research to produce 100% functionally sterile triploid progeny by fertilizing eggs from diploid females with sperm of a tetraploid males (Liu et al. 2004).

CONCLUSION

Considerable progress towards cost effective enhancement of the NSW abalone fishery has been made through reducing costs of production and transportation of *H. rubra* seed and from the identification of button size, 6–9-mo-old juveniles as the most appropriate class of seed for enhancing depleted subpopulations. The detection of a major apparent flaw in the use of clustered deployment of these juveniles and development of low density dispersed seeding technology is also a significant step forward. This will hopefully enable seeding to be aligned with surface grazing based on carrying capacity limitations of CCA rock habitats in relation to juveniles up to at least 12 mo old and 25 mm SL.

Nevertheless, many other major questions and issues remain to be addressed. Foremost is the issue of matching seeding operations with inherent capacities of individual depleted reefs to sustainably yield higher quantities of marketable 4+-year-old adults. Division of the NSW abalone fishery into six geographical management zones (Fig. 12) reflects a very steep south to north gradient of decreasing abundance of *H. rubra*. Almost 80% of TACC quotas are taken on average from zones 4–6 that collectively fall within 150 km of the Victorian border (Cape Howe). At the opposite extreme, catches from zone 1, that stretches 600 km north from Jervis Bay to the Queensland border, have fallen from around 20% of total commercial landings in the mid 1980s to only about 5% over the recent years (Anon. 2002). The relative importance of such interactive factors as recruitment, availability of food, primarily drift seaweed (Shepherd & Hearn 1983), competition for food and shelter and differential mortality factors, including natural predation and fishing pressure, plus disease (especially *Perkinsus*) on this changing pattern of abundance, is not well understood.

Higher sea temperatures in the north are undoubtedly a greater constraint to full development of gonads and hence to successful spawning and recruitment in some years. These processes require at least 1,200 degree days at moderate temperatures in the range 8°C to 18°C (Grubert & Ritar 2003). Likewise, losses of up to 90% of stocks in the Port Stephens area of zone 1 in 2000 and 2002, attributed to stress-induced susceptibility of *H. rubra* to the disease *Perkinsus*, could, together with impaired breeding, be linked to increased water temperatures. This condition has also been suggested by Shepherd et al. (1998) as a possible cause of the decline of another abalone fishery.

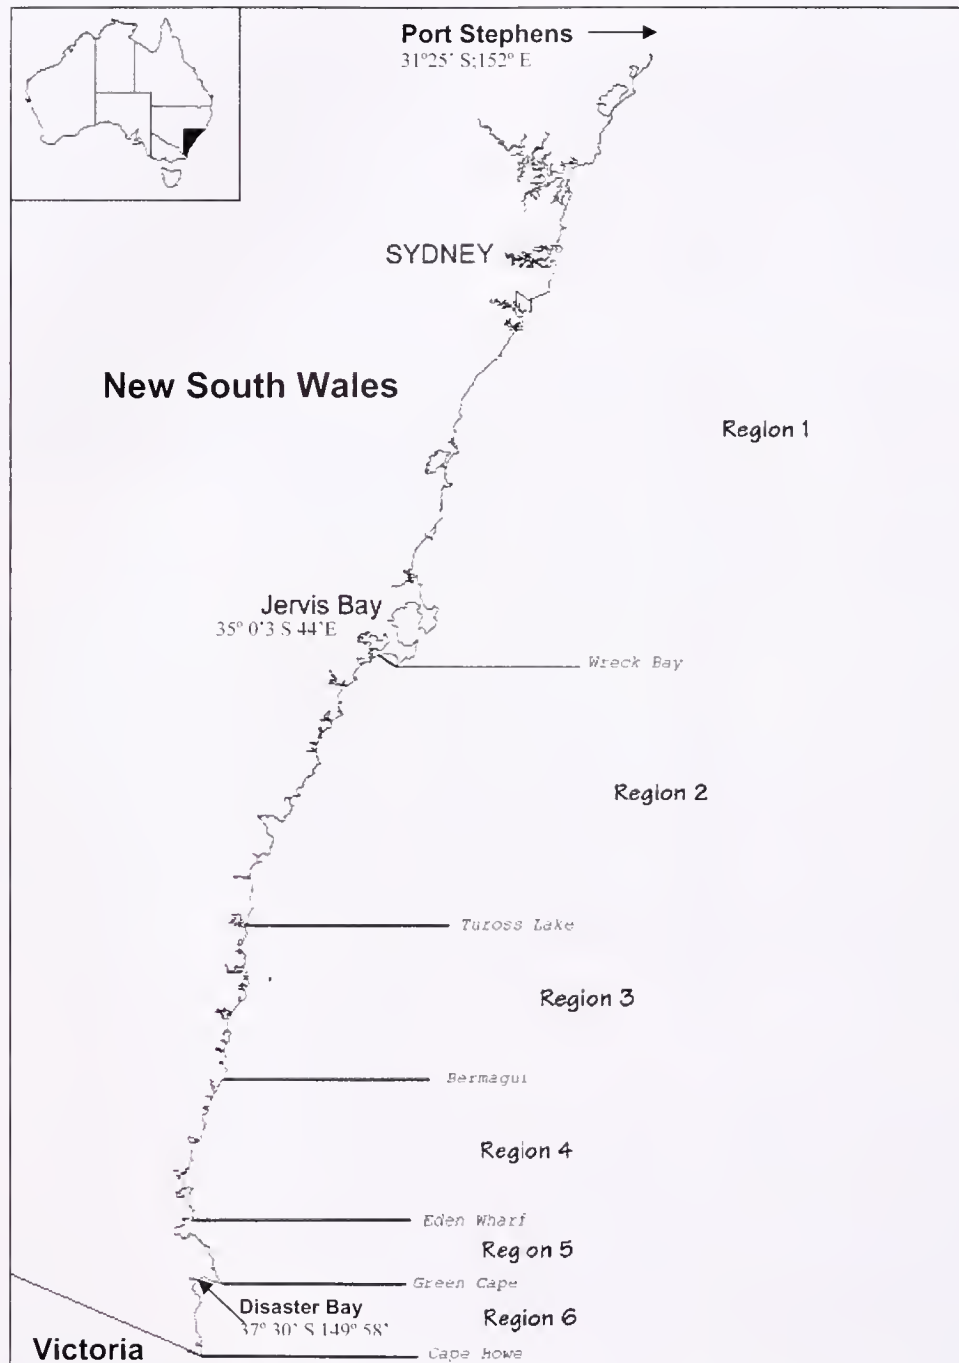

Figure 12. Map of New South Wales coastline from Port Stephens south to the Victorian border, showing abalone fishery zones.

Future development of tetraploid *H. rubra* offers the prospect of using functionally sterile 100% triploid seed to enhance depleted reefs. This could in turn enable "put and take" ranching in NSW, capitalizing on large-scale, cost efficient, centralized production of seed. Home ranges of *H. rubra* and natural recruitment in relation to parent stock, have both been shown to be limited to scales of several hundred meters in *H. rubra*. Likewise, productivity of particular areas of reef can vary greatly over distances of hundreds or even tens of meters. Effective management protocols therefore need to be tailored to accommodate these fine spatial scales.

In addition to a put-and-take ranching of sterile triploid seed,

there seems to be good scope for rebuilding depleted natural populations of *H. rubra* in NSW. However, for that strategy, seed will need to be produced in hatcheries from genetically matched parent stock in sufficient numbers to safeguard the integrity of natural gene pools, including preservation of rare or unique alleles. Rebuilding standing stocks of *H. rubra* to high levels at which self sustaining natural recruitment can be restored, will probably require integration of seeding with new and innovative fisheries management initiatives. Such initiatives will need to address apparent imbalances that have developed between *H. rubra* and several of its major competitors, especially the black urchin *C. rodgersii* and other large and common grazing gastropods, especially

Turbo torquatus (Gmelin, 1791), *Turbo militaris* (Reeve, 1848) and *Astraliun tentoriformis* (Jonas, 1845). This in turn can only be achieved through the comanagement of these competing species (Andrews et al. 1998). In contrast to *H. rubra*, black urchins and the other common gastropods cited earlier have not to date been subjected to substantial levels of fishing pressure in NSW. It is also likely that efficient reseeding protocols will need to be aligned to the patchy distribution of legal size adults. In practice this will entail targeted reseeding of juvenile habitat that lies adjacent to high yielding patches of reef. Such "hot spots" for abalone and drift seaweed are well known to experienced commercial divers and are commonly characterized by fast growing abalone with elongated shells (Worthington & Andrew 1997).

ACKNOWLEDGMENTS

The author thanks Nick Savva, Rowan Chick, John Diemar, Duncan Worthington, Craig Brand and Peter Gibson for their individual and collective contributions in the implementation of the research undertaken; the TACC quota holders for their practical and financial support of the project, with special reference to John Smythe; Mr. Peter Dundas-Smith, Dr. Patrick Hone and Dr. Ann Fleming, for their unwavering support provided through the Abalone Sub-Program; Dr Greg Maguire, Dr Wayne O'Connor and Mr. Mark Booth for reviewing the manuscript and Mrs. Helena Heasman who assisted with manuscript preparation. Fisheries Research & Development Corporation funded this research.

EXPRESSED SEQUENCE TAG ANALYSIS OF GENES EXPRESSED DURING DEVELOPMENT OF THE TROPICAL ABALONE *HALIOTIS ASININA*

DANIEL J. JACKSON AND BERNARD M. DEGNAN*

School of Integrative Biology, University of Queensland, Brisbane QLD 4072 Australia

ABSTRACT The tropical abalone, *Haliotis asinina*, is an ideal species to investigate the molecular mechanisms that control development, growth, reproduction and shell formation in all cultured haliotids. Here we describe the analysis of 232 expressed sequence tags (EST) obtained from a developmental *H. asinina* cDNA library intended for future microarray studies. From this data set we identified 183 unique gene clusters. Of these, 90 clusters showed significant homology with sequences lodged in GenBank, ranging in function from general housekeeping to signal transduction, gene regulation and cell-cell communication. Seventy-one clusters possessed completely novel ORFs greater than 50 codons in length, highlighting the paucity of sequence data from molluscs and other lophotrochozoans. This study of developmental gene expression in *H. asinina* provides the foundation for further detailed analyses of abalone growth, development and reproduction.

KEY WORDS: abalone, EST, Lophotrochozoan, development, *Haliotis asinina*

INTRODUCTION

Abalone (*Haliotis* spp.) are a particularly attractive aquaculture species because of their high demand, high market value and limited supply (Gordon & Cook 2001, Oakes & Ponte 1996). Whereas temperate abalone form the majority of abalone exports worldwide, there is a growing demand for tropical species (Jarayabhand & Paphavasit 1996). The tropical Indo-Pacific, including Australia, is well positioned to capture and further develop this market through the aquaculture of the rapidly growing tropical species *Haliotis asinina* Linnaeus. This species reaches marketable size far quicker than the temperate species (Capinpin & Corre 1996, Capinpin et al. 1999) and is ideal for the new "cocktail"-sized abalone market (Nateewathana & Hylleberg 1986, Singhagraiwan & Doi 1993).

We have been using the tropical abalone to address questions pertaining to development (e.g., Giusti et al. 2000, Hinman & Degnan 2002, Hinman et al. 2003, O'Brien & Degnan 2002a, 2002b, O'Brien & Degnan 2003, Jackson et al. 2005) and as a model to investigate the molecular basis of commercially important developmental and physiological traits (Jackson et al. 2005, Selvamani et al. 2001, Selvamani et al. 2000). With a frequent and predictable spawning cycle (Counihan et al. 2001, Jebreen et al. 2000) and established techniques for culturing to sexual reproduction (Jackson et al. 2001), gene expression can be easily studied at any stage of the life cycle. As a member of the Lophotrochozoa, the least investigated bilaterian superphylum (Adoutte et al. 2000), analyses of *H. asinina* development also contributes to a general understanding of metazoan evolution and development.

As a prelude to the sequencing of the human genome, over 170,000 ESTs were sequenced in an attempt to identify new genes and their expression patterns (Adams et al. 1995). This approach has been applied to a wide range of species, permitting the identification of homologous genes from organisms not previously studied (see http://www.ncbi.nlm.nih.gov/dbEST/dbEST_summary.html for a comprehensive list). Included in this public database are a number of marine invertebrates: the ascidians, *Ciona intestinalis* (684,319 ESTs), *Halocynthia roretzi* (4192 ESTs) and *Polyandrocarpa misakiensis* (465 ESTs), the lancelet *Branchiostoma floridae* (277,538), the sea urchin *Strongylocen-*

trotus purpuratus (130,988 ESTs), the oyster *Crassostrea virginica* (9018 ESTs) and the prawn *Penaeus monodon* (1611 ESTs) (dbEST release July 22, 2005). However there is a significant bias in this database towards vertebrates, model organisms and terrestrial species of commercial value. Here we describe a small-scale EST analysis of cDNAs obtained from a cDNA library constructed from a range of developmental stages of the tropical abalone *H. asinina*.

MATERIALS AND METHODS

RNA Extraction and Library Construction

Total RNA was extracted according to the method of Chomczynski and Sacchi (1987) from the following developmental stages: egg, gastrula, early trochophore (13 h post fertilization; hpf), mid torsion (18 hpf), early veliger (24 hpf), mid veliger (40 hpf), early competent veliger (72 hpf), late competent veliger (134 hpf), 1 day post metamorphosis and 5 days post metamorphosis. All RNAs were quantified spectrophotometrically and quality-assessed by inspection of samples that had been electrophoresed through a 1% formaldehyde gel (Sambrook & Russell 2001). To maximize gene representation in the cDNA library 200 ng of total RNA from each stage was combined for library construction using the directional Clontech SMART cDNA library synthesis kit. Following the manufacturers instructions, double stranded cDNA was PCR amplified for 23 cycles prior to cloning. Five-thousand plaques were individually hand picked following methods outlined by Sambrook and Russell (2001) for microarray printing. Of these 288 plaques were PCR amplified using the λ Triple X forward (CTCGGGAAGCGCGCCATTGTGTTGGT) and reverse (TAATACGACTCACTATAGGGCGAATTGGCC) primers. Successful PCR reactions were subsequently purified with the Millipore multiscreen PCR clean up kit. Two-hundred and thirty-two clones were single-pass sequenced using the λ Triple X forward primer and ABI Big Dye terminator mix (version 2) following standard procedures (2001).

Sequence Analysis

Sequencing chromatograms were assessed manually using 4Peaks (v1.5) and were truncated to eliminate ambiguous terminal base calls and vector sequence. BLASTx and BLASTn homology searches were conducted against the NCBI nr databases using the

*Corresponding author. E-mail: b.degnan@uq.edu.au

default conditions (low complexity filter on, an expect value of 10 and the BLOSUM62 matrix with existence 11 and extension 1 gap costs). Sequences that returned BLAST matches with an E value of $1e^{-06}$ or less were considered significant, and allowed a functional classification to be loosely made following the scheme of Lee et al. (1999). To assess sequence redundancy or "uniqueness," sequences were clustered using ClustalW (<http://www.ebi.ac.uk/clustalw/index.html?>), (Chenna et al. 2003). The integrity of each cluster was assessed manually by visually inspecting cluster alignments for overlap quality. Where cluster members were found to share more than 95% identity the cluster was usually maintained.

ESTs were also assessed for the presence of a putative poly (A) tail and an associated polyadenylation signal based on the classification of Beaudoin et al. (2000). Those sequences that did not return any significant BLAST result were assessed for the presence of an open reading frame (ORF) using the European Bioinformatics Institute Transeq server (<http://www.ebi.ac.uk/emboss/transeq/>). Only ORFs longer than 50 amino acid residues were accepted (Lee et al. 1999, Lehninger et al. 1993).

RESULTS

The *Haliotis asinina* developmental cDNA library contained 5×10^7 pfu/mL, of which approximately 93% were recombinant clones. These had an average insert size of 1044 ± 411 bp. Clustering of the 232 sequences revealed that 157 sequences occurred only once, 16 sequences occurred twice, 3 sequences occurred

three times, 3 sequences occurred four times, 3 sequences occurred 5 times and 1 sequence occurred 7 times, producing 183 unique clusters (Table 1).

Homology searches using the BLASTx and BLASTn algorithms were conducted for all sequences. 90 clusters returned a significant BLAST result and are grouped according to function in Table 2. Sixty-eight clusters fell into the category of genes used by many cell types, 8 clusters showed homology with genes involved in cell-cell communication, 3 clusters showed homology with transcription factors, and they are likely to play important developmental or biosynthetic roles in *H. asinina*. Eleven clusters showed significant homology with an undescribed ORF and could not be classified (Fig. 1; Table 1). These EST sequences have been submitted to GenBank under accession numbers DY402832–DY403158.

Polyadenylation Signal and ORF Analysis

Of the 183 unique clusters, 81 were completely sequenced in one pass and possessed a poly (A) -rich region at the 3' end of the sequence. Of these 81, 54 possessed a putative polyadenylation signal a mean distance of 17 nucleotides upstream of the poly (A) tail. The frequency of polyadenylation signals alternative to the predominant AATAAA signal was remarkably similar to that of human signals reported by Beaudoin et al. (2000) (Table 3). We also found that out of all ESTs with a polyadenylation signal, 5 (2.1%) had dual polyadenylation signals an appropriate distance

TABLE 1.
Summary of ESTs grouped by category and BLAST results.

Code Class		No. of Clusters	No. of Clones
A. Functions that many kinds of cells use			
AI	Transport and binding proteins for ions and other small molecules	1	1

* Indicates gene names that do not belong to the most significant BLAST match for that EST. The presented gene name is taken from the next most significant BLAST match that allowed classification.

Numbers in bold parenthesis represent the total number of clones in that cluster.

upstream (both within 35 bp) of the poly A tail. This compares with 16.6% of human genes with dual polyadenylation signals reported by Beaudoin et al. (2000).

Of the 93 clusters that did not produce a significant BLAST result, 71 possessed ORFs equal to or longer than 50 codons (150 nucleotides), suggesting that they represent transcribed genes with no reported homologue.

DISCUSSION

A decade ago Adams et al. (1995) established a set of stringent criteria for selection of cDNA libraries of adequate quality to be used in a large scale human EST analysis. These criteria included the following parameters: (1) less than 20% of the clones in library should have no insert or ribosomal and mitochondrial sequences; (2) the average insert lengths should be 1 kb or greater; (3) at least 50% of the cDNAs should encode novel genes and (4) no gene or

group of genes should dominate the distribution. These authors advocate the sequencing of 100–200 clones as an excellent means of assessing library quality based on these criteria. Here we have constructed a cDNA library from 10 distinct stages of development from the tropical abalone *Haliotis asinina*. Upon sequencing 232 randomly selected clones, we found that this library satisfies all of the criteria outlined by Adams et al. (1995). Searching the NCBI databases using the BLAST algorithms, 90 of the 183 clusters (49.1%) are significantly similar to previously described sequences.

As Lee et al. (1999) points out, one of the great advantages of an EST analysis of a novel cDNA library constructed from relatively poorly studied tissues is the generation of probes for "interesting" genes. This study has revealed a number of ESTs that deserve further investigation in terms of their temporal and spatial expression profiles, and the developmental and physiological roles

Figure 1. Prevalence of abalone ESTs grouped according to function.

that they play in the tropical abalone. For example, a significant proportion of the ESTs encode proteins that appear to be involved with stress response, detoxification, cell defense and innate immunity (Fig. 1). Analyses of differential gene expression in the as-

cidians *Boltenia villosa* and *Herdmania momus* during larval development and metamorphosis have revealed that a significant proportion of the expressed genes are involved with the innate immune system, with most of these being up-regulated during metamorphosis (Davidson & Swalla 2002, Woods et al. 2004). Components of the innate immune system may therefore be responsible for recognizing and responding to bacterial settlement cues associated with a suitable settlement environment. Bacterial biota associated with coralline algae may be responsible for induction of abalone settlement and metamorphosis (Bryan & Qian 1998, Roberts 2001).

Genes involved in cellular metabolism are also well represented in this EST set (7 clusters). Because larvae of *H. asinina* are lecithotrophic (nonfeeding), maternal energy reserves are utilized during larval development and metamorphosis. Genes encoding certain digestive enzymes however only appear to be activated during late larval development (Degnan et al. 1995, Spaulding & Morse 1991), whereas enzymes required for algal digestion are not detectable until postlarvae are significantly older (Takami et al. 1998). The proteases and metabolic enzymes identified here provide a platform from which to further our understanding of the processes that regulate and limit larval and juvenile growth.

An FMRF-encoding gene was also detected in this EST survey. In the gastropod mollusc *Lymnaea stagnalis*, expression of this gene is affected by infection of a schistosome parasite. This seems to be a strategy of the parasite to induce physiological (growth and reproduction) and behavioral changes in the host (Hoek et al. 1997). Among natural populations *H. asinina* can become infected by a digenaeal parasite that has been suggested to influence the antagonism between growth and reproduction cycles (Lucas et al. 2005), with infected animals effectively being castrated. The FMRF-neuropeptide identified here provides a means with which to study this phenomenon (Rice & Degnan, unpublished data).

Of the 90 unique clusters that returned significant BLAST

TABLE 3.

Prevalence of polyadenylation signals among abalone and human mRNA transcripts.

Polyadenylation Signal	Prevalence (%) and Location ¹ in Abalone ESTs	Prevalence (%) and Location ¹ in Human ESTs

ATGAAA ²	(4.1) 18 ± 2.8	—
AGAAAA ²	(2.0) 16 ± NA	—
Total	100%	87%

¹ The location reported here is the position of the sixth nucleotide of the hexamer relative to the beginning of the poly A tail.

² These 3 hexamers were not reported by Beaudoin et al. (2000) but are included here as they only differ by one nucleotide from recognized polyadenylation signals, and were located within 30 nucleotides of the poly A rich 3' region, suggesting that they may be alternative abalone polyadenylation signals.

matches, 11 (12.2%) could not be assigned a function. This value is less than that reported by Adams et al. (1995) for a human EST study (24.8% of 266,714 ESTs), but much larger than 5.2% reported by Lee et al. (1999) for a sea urchin EST analysis, and 4.1% reported by Davidson and Swalla (2002) for an ascidian EST analysis. These figures reflect both the exponential increase in the number of annotated sequences housed in the NCBI database since 1995 (the 1995 Genbank database was 3.7% the size of the 2001 database), and the fact that *H. asinina* belongs to the poorly studied Lophotrochozoan clade in terms of sequence representation and annotation.

After an analysis of those ESTs that showed no homology with any sequences in the GenBank database, Lee et al. (1999) estimated that 65% to 80% of these sequences were genuine protein coding sequences that were simply too divergent to match anything in the largely mammalian GenBank database. This estimate was based on an analysis of observed versus expected ORF length within each EST. Briefly, randomly generated sequences equal in length to those ESTs analyzed were assessed for the presence of the longest ORF. These derived ORFs rarely exceeded 150 base pairs. Here we analyzed novel clusters (clusters that showed no homology with GenBank sequences) for the presence of ORFs greater than 150 nucleotides in length, in an effort to identify genuine coding transcripts that have no homologues within GenBank. Of the 93 novel clusters, 71 (76.3%) possessed an ORF in excess of 50 codons. This is similar to Lee et al.'s (1999) estimate of *Strongylocentrotus purpuratus* specific mRNAs of 65% to 80%.

Current developmental studies on *H. asinina* further support the notion of a high proportion of *H. asinina* specific genes (Jackson et al. 2005). Interestingly, studies on *C. elegans* and *Drosophila*, for which entire genomes are available, have revealed lower estimates of organism-specific coding sequences: 50% and 30% respectively of all recognized coding sequences (Harrison et al. 2002). If representative, this high proportion of novel coding mRNA transcripts for *H. asinina* further highlights the need for more studies of this kind to be conducted on the poorly studied Lophotrochozoan clade.

CONCLUSION

This small EST project has demonstrated that the *H. asinina* library we have constructed consists of a diverse set of cDNAs that are of a large enough size to be useful in future microarray and gene characterization studies. It has also shown that during development, embryos and larvae of the tropical abalone express genes involved in a range of functions, ranging from cell defense and innate immunity to signal transduction and metabolism. The percentage of EST sequences that do not have homologues in the NCBI database highlights the need for further EST projects to be conducted on more diverse organisms, especially taxa belonging to the Lophotrochozoa.

DISEASES OF PEARL OYSTERS AND OTHER MOLLUSCS: A WESTERN AUSTRALIAN PERSPECTIVE

J. B. JONES* AND J. CREEPER

Department of Fisheries, Government of Western Australia, P.O. Box 20,
North Beach, WA 6920, Australia

ABSTRACT Mollusc culture, particularly the cultivation of pearl oysters, is an important component of the aquaculture industry in Western Australia. As a result, there has been a long-term investment in surveys of commercial mollusc species for potential diseases of concern. A number of pathogens, particularly haplosporidians, identified within wild-stock shellfish have the potential to adversely affect mollusc populations. Others pose risks for translocations associated with aquaculture. The microsporidan *Steinhausia mytilovium* (Field), found in ova of the blue mussel *Mytilus galloprovincialis* (Lamarck), poses intriguing questions about the origin and dispersal of its host.

KEY WORDS: abalone, ciliates, parasites, *Perkinsus*, Thraustochytridea, scallops

INTRODUCTION

The most valuable of the marine mollusc culture industries in Western Australia is pearling. The main species cultured is the golden-lipped pearl oyster *Pinctada maxima* (Jameson), but other pearl shells grown commercially include *P. margaritifera* (L.), *P. albina* (Lamarck) and *Pteria penguin* (Röding). The pearling industry is supported by four operational hatcheries capable of supplying all of the spat requirements of industry. Western Australia also has a small mussel industry based on culture of *Mytilus galloprovincialis*; an abalone culture industry based on hatchery produced *Haliotis* spp. (greenlip abalone, *H. laevis* (Donovan), brownlip abalone, *H. conicopora* Peron and Roe's abalone, *H. roei* Gray); a rock oyster farm hatching and growing *Saccostrea* sp.; a hatchery producing scallops (*Amusium balloti* Bernardi) for re-seeding and there is also some experimental re-seeding of tropical reefs with hatchery produced trochus (*Tectus niloticus* [L]).

Because of this aquaculture activity, the disease status of these Western Australian molluscs is relatively well known. To date there have been few diseases of concern. The health status of the aquaculture industry in a State such as Western Australia is based on two factors. The first is the presence of a disease reporting procedure and a diagnostic capacity to identify causative agents. The second is the existence of passive and targeted surveillance programs aiming to identify endemic diseases not associated with morbidity or mortality. In Western Australia a dedicated fish disease diagnostic unit of the Department of Fisheries has worked with industry since 1988 to identify and solve disease problems. There have also been 3 major mollusc disease surveys in the State; one involved a wide range of molluscs around the coast (Hine & Thorne 2000), one on *P. maxima* (Humphrey et al. 1998) and an ongoing national survey of abalone diseases. Some additional information is available in isolated publications on individual parasites and further unpublished information is available from laboratory records. Parasites that are known from shellfish in Western Australia are listed in Table 1.

Pearl Oysters

The disease that has caused most economic loss to the *P. maxima* industry is vibriosis (Pass et al. 1987). In the 1980s *Vibrio* spp. bacteria caused significant losses to the pearling industry that

have now been overcome by improved management practices. The presence of a very rare haplosporidan in the digestive tubules is cause for concern (Hine & Thorne 1998) because very little is known about the biology of this parasite. The haplosporidan has been identified only three times and each time the oysters on the infected farm site have been destroyed. During the second occurrence, in late December 1995, 4.6% of a sample of 150 farmed juvenile pearl oysters was found infected within 6 weeks of being set at a remote site in Western Australia. By the time the oysters were destroyed 15 days later the infection prevalence had increased to 10% ($n = 238$). The notifiable disease *Perkinsus olseni*/atlanticus has been reported from *P. maxima* in the Torres Strait (Norton et al. 1993a) but not from Western Australia, though the disease agent does occur here in bivalve molluscs other than *P. maxima* (Table 1).

Another parasite of concern in pearl oysters has only been detected in spat from the Exmouth Gulf and outlying islands since 2001, despite comprehensive monitoring of oysters in the State and the industry practice of harvesting and translocating shell to all other oyster growing areas for over 50 y. It is an intracellular ciliate similar in appearance to ciliates reported as nonpathogenic commensals in Spanish *Mytilus galloprovincialis* (Villalba et al. 1997) and in *Mytilus edulis* (L) on the east and west coasts of North America (Figueras et al. 1991a). The teardrop shaped basophilic ciliate (10–15 $\mu\text{m} \times 5 \mu\text{m}$) has a dense polymorphic macronucleus and normally occupies an intraluminal or intraepithelial location within the digestive gland in *P. maxima* spat (Fig. 1). The ciliate is often associated with an inflammatory response in oysters smaller than 70 mm with 20–50 mm shell being most affected. A feature in smaller (20–40 mm) spat is the ciliate's capacity to penetrate the mucosal basal lamina and reside within hemolymph spaces or free within interstitial connective tissue. Translocation of infected pearl oysters beyond the Exmouth zone is not permitted.

The origin of the ciliate is unknown, and its relationship to similar organisms seen in northern hemisphere mussels is unknown. Either the ciliate has become much more prevalent in recent years or it has been introduced into the region. Its infectivity to other bivalves is also unknown.

During surveys to determine the distribution of the ciliate, a single infected oyster was found with an enigmatic unidentified proctistan parasite (Fig. 2). The putative sporoblasts develop within the epithelial cells of the digestive tubules and fill the lumen of the tubules, with an associated basophilic hemocyte inflamma-

tory response. With a prevalence of less than 0.005% it is not feasible to attempt follow-up sampling, but it does indicate that parasitic organisms can be present at extremely low prevalence in a population.

Another proctistan was detected at a low prevalence in *P. maxima* from the Exmouth Gulf during investigations into the ciliate parasite. The parasite was elongated (30 $\mu\text{m} \times 20 \mu\text{m}$) and intimately associated with the digestive gland epithelial cells to which it appeared to have a sessile attachment (Fig. 3). The tubule epithelial cells beneath the site of attachment were multinucleated and ultrastructural examination indicated the multiple nuclei were of molluscan origin, suggesting the proctistan had induced this change within the host.

Figure 1. Ciliate in digestive tubules of *Pinctada maxima* spat from Exmouth Gulf (arrow). H&E, scale bar = 10 μm .

A proctistan tentatively attributed to the Thraustochytridea was identified in moribund, gaping *P. maxima* from a farm that had experienced losses after a cyanobacterial (*Trichodesmium* sp.) bloom. The affected oysters showed extensive necrosis of external epithelial surfaces of the palps and mantle with invasion of the underlying leydig tissues by brown pigmented and eosinophilic, segmented unicellular organisms 10–15 μm in diameter, and smaller dense basophilic 5- μm diameter cells that appeared to be embedded in a mucinous matrix (Fig. 4).

Rock Oysters

One of 411 *Saccostrea glomerata* (Gould) collected between Carnarvon to the Dampier Archipelago during 1995 was infected

Figure 2. Unidentified proctistan parasite (arrow) in pearl oysters *Pinctada maxima* from Exmouth Gulf. The parasite fills the digestive gland. H&E, scale bar = 30 μm .

Figure 3. A large protistan intimately attached to digestive tubule epithelial cells by apparent cytoplasmic attachments with hyperplasia of tubule nuclei, in *Pinctada maxima*. H&E, scale bar = 10 µm.

with a parasite histologically identical to *Marteilia sydneyi* Perkins and Wolf, the cause of QX disease in *Saccostrea commercialis* (Iredale and Roughley) in Queensland and New South Wales. The same pathogen was also found in *S. glomerata* by Hine and Thorne (2000). On the eastern seaboard where QX occurs, it has caused losses of over 90% (Witney et al. 1988) and has resulted in a decline in New South Wales rock oyster production since the 1970s.

S. cucullata (Born) from Airlie Island, Rosily Island, Varanus Island, Hermite Island, King Bay and East Lewis Island in the

north of Western Australia are infected by a second species of pathogenic haplosporidan protozoan, *Haplosporidium* sp. The parasite was identified as the cause of a significant mortality (up to 80%) of rock oysters at Airlie Island (Hine & Thorne 2000). The presence of this haplosporidan will threaten the viability of any rock oyster farm sited north of Exmouth.

Mussels

The ova of mussels in Cockburn Sound, Western Australia are infected with the microsporidan *Steinhansia mytilorum* but the parasite has not been found in mussels from other growing areas. Heavily infected mussels are readily identified by the gross appearance of the mantle of cooked females. Infected mantle tissue has an uneven surface with depressed cream white patches and swollen tubercles forming spots against the orange-pink background color of healthy female gonad. Mussel samples in August and October 1995 from sites around the Sound showed a prevalence of *Steinhansia* sp. ranging from 22% to 57%, or 44.4% overall. Histology revealed that the patches and tubercles were associated with a marked infiltration of circulating granulocytes and large basophilic hemocytes into affected follicles with resorption of the germinal epithelium and ova (Fig. 5). Small basophilic hemocytes were not prominent in the response. Also present in 2% to 4% of the ova were parasitophorous vacuoles closely associated with the nucleus. These vacuoles measured 13.27 ± 2.37 µm ($n = 20$) and contained over 30 small spores 2.5-µm diameter. There was usually only one vacuole in an ovum, but occasionally up to three parasitophorous vacuoles could be seen. In histological sections the presence of resorbing follicles and focal accumulation of granulocytes among the developed ova was evidence of infection, but infected oocytes were also observed in apparently healthy follicles. Ova (normal, infected and degenerating), granulocytes, large basophilic granular hemocytes and cell debris occurred in the ciliated gonad ducts. Parasitophorous cysts containing spores also occurred free in the lumen of the ducts. The spore walls and contents stained negative to Feulgen, Ziehl-Neelsen and Grocotts, were Gram positive and Periodic-Acid-Schiffs negative.

Figure 4. Large 15 µm dia. segmented retractile eosinophilic cells and smaller 5-µm basophilic cells within the leydig tissues of *Pinctada maxima*, tentatively attributed to a thraustochytrid. H&E, scale bar = 20 µm.

Figure 5. *Steinhansia mytilorum* in *Mytilus galloprovincialis* from Cockburn Sound, Western Australia (arrows), main picture and insert. Note inflammatory response in main picture. H&E, scale bar = 10 µm.

The relationship between this *Steinhausia* sp. and the one previously described by Anderson et al. (1995) from cysts within ova of the rock oyster *S. commercialis* in Queensland, Australia is unknown. The biology of *Steinhausia* sp. is not well understood. Field (1923) reported that infected eggs were shed along with normal eggs. Sparks (1985) suggested that infected eggs do not seem to become necrotic or degenerate though Rybakov and Kholodkovskaya (1987) noted that *Steinhausia* sp. clearly distorts the nucleus of the ovum and can also cause the destruction of the egg, as has been seen in Western Australian mussels. It is likely that the loose spores are released along with intact eggs or through phagocytosis and subsequent diapediasis. Figueras (1991) reported that the presence of the parasite is always accompanied by a strong hemocytic response and the impact on the host has been described as severe (Rybakov & Kholodkovskaya 1987) to negligible (Maurand & Loubès 1979). In the case of the *S. mytilorum* infection seen here, there is an absence of the typical bivalve inflammatory response, which involves invasion of the site of trauma primarily by small agranular hyalinocytes (90%), granular basophils (8%) and granular acidophils (2%) (Bayne et al. 1979, Brereton & Alderman 1979). Instead the major components are the phagocytic hemocyte and the granular acidophil and the process closely resembles gonad resorption. Prevalence of *Steinhausia mytilorum* does not increase with the size of the mussel, suggesting that infection is annual (Table 2).

The proctistan observed in the ova of Western Australian blue mussel has the same measurements and appearance under the light microscope as *S. mytilorum* from both European and American *M. galloprovincialis*. The taxonomy of the blue mussel in Western Australia is disputed. Still referred to as *M. edulis planulatus* (L.), electrophoretic studies have shown that the species is *M. galloprovincialis* and that *M. galloprovincialis* from Australasia, eastern Asia, Western Europe, the Mediterranean and California, and *M. edulis* from eastern North America and Western Europe are electrophoretically distinct species with an overlapping distribution (Koehn 1991, McDonald et al. 1991, Geller et al. 1993). There is a fossil record of mussels in Australian waters and Koehn (1991) hypothesized that *M. galloprovincialis* may have been an early introduction into the Northern Hemisphere as a hull-fouling organism. Distribution of parasites often reflects the distribution of their primary hosts so *S. mytilorum* may also be an introduction from the Southern Hemisphere. *Steinhausia mytilorum* is reported to infect the ova of *M. edulis* along the Atlantic coast of the USA (Field 1923, Figueras et al. 1991a). Sparks (1985) reported that,

based on examination of thousands of mussels, the parasite was absent from California, Oregon and Washington and it was unreported from Europe. It now occurs in *M. galloprovincialis* from Spain (Figueras et al. 1991b), Italy (De Vincentiis & Renzoni 1963), Greece (Rayyan et al. 2004), the Black Sea (Rybakov & Kholodkovskaya 1987, Gayevskaya & Machkevskiy 1991), northern France (Comtet et al. 2004) and the west coast of the USA (Hillman 1990, 1991). Hillman (1990) noted that *M. galloprovincialis* had been accidentally introduced into southern California and suggested that *S. mytilorum* had been introduced with the mussels.

Scallops

There are two nematode larvae found in scallops (*Amusium balloti*) in the Shark Bay area of Western Australia. The "common" nematode in scallops is *Sulcascaris sulcata*. This was reported by Lester et al. (1980) to infect up to 64% of the landed catch in Shark Bay and occurs in a brownish capsule 3–7 mm dia. The adult nematodes of *S. sulcata* live in the loggerhead turtle *Caretta caretta* (L.) and have a wide geographic distribution and range of molluscan hosts. The second species, *Echinocephalus* sp., forms small yellow-brown cysts 2–3 mm dia. Lester et al. (1980) reported that only 2 of 10 scallops he examined were infected, but in recent years the nematode has been much more common and in 2001 was the dominant nematode in *A. balloti*. The genus *Echinocephalus* occurs widely in molluscs in warm waters, and probably matures in marine skates or rays.

Abalone

The Western Australian component of a national health survey of abalone has recently been completed. In this survey, up to 25% of wild-caught green-lipped abalone (*Haliotis laevis*) were infected with trematode metacercariae. Low prevalences of proctistans in the lumen of the stomach and digestive gland, apicomplexans and putative viral inclusions in the intestinal tract were observed. Abalone in Western Australia are free of the disease perkinsosis, found in South Australia and New South Wales, but the organism does exist on the south coast of Western Australia. *Perkinsus* is a primitive fungus-like organism of uncertain taxonomic status, probably in the phylum Labrithulomycota. A worldwide effort to understand the taxonomy of this organism (or group of organisms) is underway. In South Australia and New South Wales *Perkinsus olseni/atlantensis* affects abalone with yellow-green pus filled blisters (0.5–8 mm dia.) containing a creamy brown deposit. Once processed the lesions appear as pale brown circles. Perkinsosis occurs in a variety of shellfish in the north of the State (Hine & Thorne 2000), however, a survey of 300 abalone from six sites along the south and west coasts of Western Australia in 1995 were negative for *Perkinsus* sp. by the thioglycolate media method. Subsequently, in 2003 *Perkinsus* sp. was cultured from the gill tissue of one clinically normal abalone (*H. laevis*) from the south coast.

FUTURE TRENDS

Whereas, overall, disease has not been a problem for the mollusc industry in Western Australia, it is certain that many more pathogenic organisms remain to be discovered, particularly as molluscs become subject to aquaculture or are subject to environmental stresses associated with economic activity. Because of the age

TABLE 2.

Prevalence of *Steinhausia* sp. in female *Mytilus galloprovincialis* from Cockburn Sound, Western Australia.

Size of host (mm)	Number infected	Total number examined	% infected
<50	16	34	47.0
50–59	33	65	50.7
60–69	23	80	28.7
70–79	93	189	49.2
80–89	51	114	44.7
>90	7	10	70.0
Overall	223	492	45.3

There is no increase in prevalence of infection with mussel size.

of the Australian continent and the relative isolation of the coastal fauna it is likely that many of these will prove to be unique to Western Australia. Strict controls are therefore imposed to limit translocation of parasites by aquaculture. Whereas these pathogens may represent an economic threat, it is probable that they will also provide new insights on the zoogeography and derivation of the Western Australian mollusc fauna.

ACKNOWLEDGMENTS

The authors thank the shellfish industries in Western Australia for their assistance in providing specimens and Paul Hillier and Tina Thorne for help in collecting mussels. Melanie Crockford, Greg Maguire and Fran Stephens provided editorial comment.

GROWTH AND SURVIVAL OF JUVENILE GREENLIP ABALONE (*HALIOTIS LAEVIGATA*) FEEDING ON GERMLINGS OF THE MACROALGAE *ULVA* SP

LACHLAN W. S. STRAIN,¹* MICHAEL A. BOROWITZKA¹ AND SABINE DAUME²

¹School of Biological Sciences & Biotechnology, Murdoch University, South Street, Murdoch, WA 6150, Australia; ²Research Division, Department of Fisheries, Western Australia, PO Box 20, North Beach, WA 6920, Australia

ABSTRACT Germlings of the green alga *Ulva* sp. were developed as a diet for juvenile *Haliotis laevis* (≥ 3.5 mm shell length) and compared with a current commercial diet consisting of *Ulva* sp. plus the diatom species *Navicula* cf. *jeffreysi*. The utilization of macroalgae germlings (juvenile gametophyte and sporophyte) allowed 3-dimensional growth and subsequently provided greater feed biomass in comparison with the current 2-dimensional commercial feed for the later nursery phase consisting of 5–10 mm (shell length) juvenile abalone. The juvenile abalone showed active feeding on both the *Ulva* germling diet and the current commercial diet. The *Ulva* sp./*Navicula* cf. *jeffreysi* diet resulted in abalone of significantly larger shell length at the end of the 14-wk feeding trial. However, the *Ulva* germling diet recorded significantly larger abalone for the first 4–5 wk, whereas the commercial diet produced significantly larger abalone from week 6 to the end of the trial. The growth rate on both diets exceeded $100 \mu\text{m} \cdot \text{day}^{-1}$ and the specific growth rates were maintained above $1\% \cdot \text{day}^{-1}$ for the duration of the feeding trial with neither measure portraying significant differences between diets. There was no significant difference in juvenile abalone mortality feeding on the two diets. The *Ulva* germling consumption exhibited a spike ($500 \text{ germling blades} \cdot \text{abalone}^{-1} \cdot \text{day}^{-1}$) in consumption at week three then, once reduced, a gradual increase occurred until the end of the trial. *Ulva* sp. consumption demonstrated a similar pattern to *Ulva* germlings consumption and was significantly, positively correlated. Consumption rates for the two green algae both correlated with juvenile abalone growth. The diatom (*Navicula* cf. *jeffreysi*) consumption was affected by plate rotation (light intensity and grazing pressure) rather than juvenile abalone.

KEY WORDS: juvenile abalone, *Haliotis laevis*, *Ulva*, germlings, *Ulva* sp., diatoms, dietary value

INTRODUCTION

To culture quality abalone to commercial harvest size within an economical time frame, current culture protocols and in particular, juvenile nutrition need to be improved. To advance this area of production, new juvenile diets must be explored that supply sufficient biomass and provide greater nutritional benefits.

The main diet of postlarval and early juvenile abalone (up to ~5 mm) in the natural environment consists of epiphytic and epilithic diatoms, crustose coralline algae, turf algae and bacteria, whereas larger juveniles consume macroalgae (Dunstan et al. 2002, Kawamura et al. 1995, Kawamura 1996, Kawamura & Takami 1995, McShane et al. 1994, Takami et al. 1998). Once abalone reach the transition phase from a diatom-based diet to a macroalgae diet, diatoms such as *Cylindrotheca closterium* (Ehrenberg) alone are no longer sufficient to maintain adequate growth rates in an aquaculture system (Takami et al. 2003). At this stage additional algal food is required to sustain maximum growth rates and reduce the variability of growth and survival rates. Maintenance of an adequate food supply to the 5–10 mm juveniles is seen as a major limiting factor in the intensification of abalone nurseries (Krsinich et al. 2000).

Currently in Australian commercial abalone nurseries, postlarvae are supplied with diatoms (e.g., *Navicula* cf. *jeffreysi*) and as they develop into juveniles they are provided with the crustose green alga *Ulva* sp. crouch (Daume & Ryan 2004, Daume et al. 2004). *U. lens* has been shown to induce higher settlement rates of abalone larvae compared with monospecific benthic diatom films (Daume et al. 2000, Krsinich et al. 2000). By itself *U. lens* only supports moderate growth rates but, when combined with an easily digestible diatom such as *N. jeffreysi*, the diet can sustain high

growth rates (Daume & Ryan 2004, Kawamura et al. 1998). Takami et al. (1997) also found that rapid abalone growth is only achievable on crustose coralline algae (*Lithophyllum yes-soense*) if diatoms are present. Once abalone exceed about 5 mm in length, the combined diet of *U. lens* and *N. jeffreysi* is unable to adequately support the high abalone biomass per plate (Daume & Ryan 2004).

A potential alternative commercial feed for juvenile abalone (5–10 mm) may be macroalgae sporelings. The majority of juvenile abalone dietary studies have been conducted with mature macroalgae; however, they may have different nutritional and structural properties to juvenile macroalgae of the same species (Van Alstyne et al. 1999). The juvenile macroalgae (germlings) can potentially provide a greater biomass per plate because of their 3-dimensional morphology compared with the 2-dimensional encrusting algae and have been shown to support moderate to rapid growth of $90\text{--}130 \mu\text{m} \cdot \text{day}^{-1}$ (Maesako et al. (1984) as cited in Kawamura et al. (1998)).

The 3-dimensional growth reduces the surface area required and gives the feed the potential to combat the juvenile abalone's ability to consume 5% to 30% of their body weight in algae each day (Corazani & Illanes 1998, Hahn 1989). *Ulva* has been used in numerous studies, both individually or as part of mixed/rotation diets but is considered a relatively poor nutrition source (Simpson & Cook 1998). Shpigel et al. (1999) has shown that specific growth rates of 0.6 to $1\% \cdot \text{day}^{-1}$ can be attained for juveniles 8–15 mm in shell length and that some abalone species grow better on *Ulva* cultured in high ammonia-N enriched seawater, underlying the importance of the feed's nutritional value.

In this study, the dietary value of an *Ulva* sp. germling diet was compared with a currently used commercial diet consisting of the green alga *U. lens* plus the diatom species *N. jeffreysi* on the growth and survival of juvenile greenlip abalone (*Haliotis laevis* Donovan).

MATERIALS AND METHODS

Location

The feeding trial was conducted in a greenhouse at the Aquaculture Development Unit, Challenger TAFE, Fremantle, Western Australia between March and August 2004. Juvenile greenlip abalone (*Haliotis laevis*) were supplied by Great Southern Marine Hatcheries in Albany, Western Australia.

Algal Culture—Diets

Ulva sp. Germling Diet

Ulva sp. thalli were collected from submerged limestone rocks on South Mole in Fremantle and exposed to a cold (4°C) treatment to induce gametogenesis. *Ulva* thalli were arranged in layers in-between moist newspaper then refrigerated. After 7 days of cold treatment, 10 kg blotted wet weight of *Ulva* thalli was placed into each of the five, 400 L tanks filled with a modified f/2 culture medium (Guillard & Ryther 1962), that lacked PII metals, sodium metasilicate and vitamin stock solutions. Each tank held 3 baskets of 12, 30 × 60 cm PVC plates lying horizontally. The tanks received only light aeration to reduce water motion and allow maximum spore attachment.

The *Ulva* thalli were removed from the five tanks after 6 days and the germling seeded PVC plates redistributed into three 400 L tanks each containing 3 baskets of 20 plates now orientated vertically. The germlings were then cultured over 5 wk in the modified f/2 medium, which was exchanged twice weekly.

Ulvella lens Plus *Navicula cf. jeffreyi* Diet

The diatom *Navicula cf. jeffreyi* (CSIRO Hobart, CS-514) was cultured in standard f/2 medium (Guillard & Ryther 1962) with cultures starting indoors in 4 petri dishes that were then scaled up through four, 1.5 L horizontally laid culture bags and finally to one, 60 L, shallow tank outdoors. 20 L of the *N. jeffreyi* inoculum was added to each of the three *U. lens* tanks.

Sixty *U. lens* seed plates (30 × 60 cm PVC) (Daume & Ryan 2004, Daume et al. 2004) were placed at regular intervals between clean 30 × 60 cm PVC plates and exposed to sunlight for 5 days, then removed. The aeration was low to allow the *U. lens* spores to attach to the plates and the modified f/2 medium was exchanged twice weekly.

Feeding Trial

For each of the 2 treatments (*Ulva* germling diet and *U. lens/N. jeffreyi* diet), three, 400 L tanks were stocked with three baskets of 20 vertically arranged seeded plates (30 × 60 cm). The tanks were aerated by three airlines spaced evenly along the bottom and shaded with 70% shade cloth; 1 µm filtered bore seawater was supplied at 10 L.min⁻¹ via a spray bar above the water surface. The water temperature over the 3 mo feeding trial started at 20.8 ± 0.13°C (May) then reduced to 19.7 ± 0.18°C (June) and finished at 19.0 ± 0.08°C (July).

Juvenile greenlip abalone (*H. laevis*) were taken off an *U. lens*/naturally occurring diatoms diet and transported (4 h) on PVC plates seeded with *U. lens* between wet sponge sheets in insulated containers. The PVC plates with juveniles attached were placed across the top of the baskets in each tank and left for 2 wk to allow the juveniles to migrate onto the experimental diet plates. Seventeen hundred juveniles of 3.5–4 mm shell length were stocked in

each of the six tanks giving approximately 28 juveniles per 30 × 60 cm plate.

The feeding trial was for a period of 14 wk and the three *U. lens* tanks were reinoculated with *N. jeffreyi* during weeks 2, 4 and 8. The plates in all tanks were rotated twice, 180° about the horizontal in weeks 3 and 10.

Measurements

Abalone shell length (mm) and weight (g) were measured at the beginning of the trial and then weekly by collecting a sub sample of 50 juveniles from 10 randomly selected plates in each tank. After the juvenile abalone had been measured the contents of each tank were siphoned through 50 µm mesh and the dead abalone counted.

Ulva germling abundance was determined by counting the number of germling blades per cm² of plate at weekly intervals. Every fifth plate was counted with 5 randomly selected fields of view (0.785 cm²) counted diagonally across the plate. The density of the *U. lens* was determined by estimating percentage cover along a graticule using the same sampling procedure as the *Ulva* germlings. The density of *N. jeffreyi* was measured on 2 removable notches cut from the side of every sixth plate. The notches were approximately 16 cm² and positioned 3 cm from the top and bottom. The number of cells present on these notches was then counted for a defined area in 20 randomly chosen fields of view and the number of cells.cm⁻² calculated.

Biochemical Analysis

Samples were taken by scraping diagonally across the plates that were used for determining weekly algal abundance. Scrapings were stored at -20°C until needed.

Algal Dry Weight

Five milliliters of the *U. lens/N. jeffreyi* samples and 0.05 g of the *Ulva* germling sample were filtered through Whatman GF/C (2.5 cm) glass microfiber filters that had been washed, precombusted and preweighed. The filtrate was then washed with 10 mL of ammonium formate solution (0.65 M) to remove excess salts, dried in an oven for 12 h (80°C) and placed in a vacuum desiccator overnight. They were then weighed to 4 decimal places on an analytical balance.

Lipid Determination

The lipid content of the algal diets were determined based on the method of Bligh and Dyer (1959) as modified by Kates and Volcani (1966) and adapted by Mercz (1994).

Five milliliters of the *U. lens/N. jeffreyi* samples and 0.025 g of the *Ulva* germling samples were filtered onto Whatman GF/C (2.5 cm) glass microfiber filters, rinsed with 10 mL ammonium formate (0.65 M) and stored at -20°C for approximately 2 mo.

Once thawed, filters were homogenized in a glass mortar and pestle with 5 mL of a methanol:chloroform:deionised water solution (2:1:0.8 v/v/v). The extract was centrifuged at 3000 rpm for 5 min and the supernatant transferred to a second, 10 mL graduated glass centrifuged tube. The volume was made up to 5.7 mL with fresh methanol:chloroform:deionised water, then 1.5 mL chloroform and 1.5 mL deionized water were added while mixing well.

The tubes were recentrifuged (3,000 rpm for 5 min), after which phase separation was complete and the lower green chloroform layer containing the lipids were carefully transferred into

dry, preweighted 4 mL glass vials. A few drops of toluene were added and the extract dried under ultra pure nitrogen. The vials were placed in a vacuum desiccator (KOH pellets) overnight and weighted to 4 decimal places.

Protein Determination

The protein content of the algal diets were determined utilizing a modification of the Lowry et al. (1951) method by Dorsey et al. (1978) and Mercz (1994). Samples were prepared as in the Lipid Determination procedure (above) with 0.0125 g of *Ulva* germlings used for each sample.

Filters were homogenized with 5 mL Biuret reagent in a glass mortar and pestle, then transferred into 10 mL graduated glass centrifuged tubes and 0.14 mL of deionized water added. Protein standards (Bovine Serum Albumin) of 0, 10, 20, 30, 40, 50, 60 and 70 μg were made up to 0.14 mL with deionized water, and 5 mL Biuret reagent was added.

All tubes were incubated at 100°C for 60 min and immediately after 0.5 mL Folin Phenol reagent was added while mixing on a Vortex stirrer. The tubes were cooled for 15 min at 10°C to 15°C and 15 min at room temperature, then centrifuged (3,000 rpm for 5 min). The absorbance of the supernatant was read at 660 nm and the protein content determined from the standard curve.

Carbohydrate Determination

The carbohydrate content of the algal diets were determined using the method of Kochert (1978) incorporating modifications by Ben-Amotz et al. (1985) and Mercz (1994). Samples were prepared as in the lipid determination procedure (earlier) with 0.012 g of *Ulva* germlings being used.

Five milliliters of H_2SO_4 (1 M) was used to homogenize filters in a glass mortar and pestle before being transferred into 10 mL graduated glass centrifuged tubes and incubated at 100°C for 60 min. After cooling to room temperature and centrifuging (3,000 rpm for 5 min) a known volume of supernatant (<50 μg total carbohydrate, which is between 0.1–0.5 mL, depending on initial algal concentration) was taken and made up to 2 mL with deionized water in 10 mL graduated glass centrifuged tubes. Carbohydrate standards (Glucose) of 0, 10, 20, 30, 40 and 50 μg were made up to 2 mL with deionized water.

One milliliter of 5% (w/v) phenol solution was added and mixed well on a Vortex stirrer. Five milliliter of concentrated H_2SO_4 (98%, 18 M) was added rapidly and then the tubes left for 30 min to cool. Absorbance was measured at 485 nm and the carbohydrate content determined from the standards.

Data Analysis

Juvenile abalone growth and density for the 2 dietary treatments *Ulva* germling and *U. lens/N. jeffreyi* were compared by analysis of variance (1-way ANOVA). A univariate analysis of variance, posthoc (Tukey HSD) test was applied to test for differences between mean abalone interval sizes (shell length) on the two diet treatments at each time interval. Comparisons of the algae diets consumption and biochemical composition were achieved through Bivariate Correlation and analysis of variance (1-way ANOVA) respectively. The plate rotation was analyzed with an Independent *t*-test.

RESULTS

Abalone Growth

At the commencement of the feeding trial there was no significant difference between the average shell lengths of the abalone

distributed to the 2 diets ($F_{(df\ 1,298)} = 0.49$ [$P = 0.484$]). The juvenile abalone grew on both diets with the *Ulva* germling diet producing significantly larger abalone (shell length) for the first 5 wk ($F_{(df\ 1,2398)} = 6.779$ [$P < 0.05$]) (Fig. 1).

During the first 4 wk the mean weekly increase in shell length of the abalone on the *Ulva* germling diet was 0.51 ± 0.1 mm with each increase shown to be significant (Table 1). The abalone on the *U. lens/N. jeffreyi* diet only averaged a weekly increase in shell length of 0.41 ± 0.1 mm for the first 4 wk but were able to maintain significant increases in shell length until week 7 (Table 1). The subsequent extended period of significantly faster growth resulted in the abalone on the *U. lens/N. jeffreyi* diet surpassing the size (shell length) of the abalone on the *Ulva* germling diet and this transition is evident in Figure 1 where the two growth profiles intersect between weeks 5 and 6. The *U. lens/N. jeffreyi* diet then proceeded to yield significantly larger abalone (shell length) ($F_{(df\ 1,2698)} = 24.671$ [$P < 0.05$]).

The weekly growth rates of juvenile abalone were very variable (reaching over $100\ \mu\text{m}\cdot\text{day}^{-1}$) on both the *Ulva* germling diet and the *U. lens/N. jeffreyi* diet during the first 6 wk (Table 1, Table 2). The *Ulva* germling diet sustained a higher specific growth rate for abalone over the first 4 wk, reaching a maximum of $1.5\%\cdot\text{day}^{-1}$ (Fig. 2).

After the 8th wk of the feeding trial, shell length was not significantly different between adjacent weeks on either diet (Table 1), indicating a reduction in absolute growth rate (Table 2) and specific growth rate (Fig. 2). From Table 2 it is evident that the *Ulva* germling diet produced slightly lower, not significantly lower, ($F_{(df\ 1,82)} = 0.583$ [$P = 0.448$]) growth rates over the entire feeding trial. Consequently, the specific growth rate of the juvenile abalone was not significantly affected by diet ($F_{(df\ 1,82)} = 1.968$ [$P = 0.164$]) with both recording $1\%\cdot\text{day}^{-1}$ by the end of the 14 wk trial (Fig. 2).

The juveniles consuming the *Ulva* germling diet were smaller at the completion of the trial with an average of 9.61 ± 0.1 mm shell length, compared with the average shell length of 10.29 ± 0.1 mm the abalone on the *U. lens/N. jeffreyi* achieved (Fig. 1). The final abalone shell lengths were significantly different indicating that the *U. lens/N. jeffreyi* diet produced significantly larger abalone than the *Ulva* germling diet ($F_{(df\ 1,298)} = 10.335$ [$P < 0.05$]).

Abalone Survival

In conjunction with growth, mortality and the subsequent abalone density are important in comparing the two diets effectiveness as a feed for juvenile abalone. Weekly mortality on both diets exhibited very similar profiles with the *U. lens/N. jeffreyi* diet producing an average of 91 mortalities in week 3 but thereafter the *Ulva* germling diet recorded slightly higher mortalities until week 10 (Table 3). Calculating the progressive abalone density from the weekly mortality indicated there was no significant difference in abalone density between the two diets ($F_{(df\ 1,88)} = 0.569$ ($P = 0.453$)). Crushed shells and escapees were unable to be considered in the weekly mortality giving a discrepancy with the final densities. Even though the number of abalone at the end of the 14 wk trial was lower on the *Ulva* germling diet, 1,948 abalone (38.2% survival), compared with the *U. lens/N. jeffreyi* diet, 2,390 abalone (46.9% survival), the difference was not significant ($F_{(df\ 1,4)} = 3.911$ ($P = 0.119$)).

Algal Consumption

The juvenile abalone consumed entire *Ulva* germlings, both blade and attachment regions. During the first month of the ex-

TABLE 2.

Weekly growth rates for juvenile *Haliotis laevis* combined into monthly periods ($n = 3$) for both an *Ulva* germling diet and an *U. lens/N. jeffreyi* diet. The first 2 weeks were excluded to allow time for the juvenile abalone to adapt to the experimental conditions and diets.

Diet	Week 3-6		Week 7-10		Week 11-14	
	Mean GR ($\mu\text{m}\cdot\text{day}^{-1}$)	SE	Mean GR ($\mu\text{m}\cdot\text{day}^{-1}$)	SE	Mean GR ($\mu\text{m}\cdot\text{day}^{-1}$)	SE
<i>Ulva</i> germling	84.1	9.5	66.1	8.7	35.7	11.8
<i>U. lens/N. jeffreyi</i>	94.1	5.0	68.2	7.5	52.9	11.7

Figure 2. Specific Growth Rate of juvenile *Haliotis laevis* on an *Ulva* germling diet and an *Ulva lens/Navicula cf. jeffreyi* diet. Mean \pm std. error ($n = 3$).

periment, consumption of germlings peaked at 500 germling blades.abalone⁻¹.day⁻¹ but by week 6 the consumption had decreased to 100 germling blades.abalone⁻¹.day⁻¹. Consumption gradually increased after that (week 6), doubling by the end of the feeding trial (Fig. 3). During the last two months there was a positive correlation between the increase in *Ulva* germling consumption and the increase in abalone shell length ($R = 0.583$; $P < 0.05$).

The consumption of *U. lens* followed a similar trend and was significantly, positively correlated ($R = 0.422$, $P < 0.05$) to the *Ulva* germling consumption but with a reduced rate of decline after the period of high consumption (Fig. 4). Consumption of *U. lens* also significantly correlated to the grow rate ($R = 0.544$, $P < 0.05$) and subsequently the specific growth rate ($R = 0.618$, $P < 0.05$) of the juvenile abalone.

Diatom consumption (Fig. 5) exhibited a similar profile to that of the *Ulva* germlings and *U. lens* consumption including the slow increase after week 7. However this increase fluctuated under or on zero diatoms.abalone⁻¹.day⁻¹ for weeks 7-12 because the positive growth of algae was greater than the consumption by abalone.

TABLE 3.

Weekly mortality of juvenile *Haliotis laevis* for both the *Ulva* germling diet and the *U. lens/N. jeffreyi* diet. Mean \pm std. error ($n = 3$). (Initial number of abalone per replicate tank was 1,700).

Week	<i>U. lens/N. jeffreyi</i>		<i>Ulva</i> Germling	
	Mean	SE	Mean	SE
1	63	5.86	71	5.81
2	81	23.16	85	22.15
3	91	22.4	56	6.44
4	64	14.19	72	12.01

6	27	2.91	59	22.21
7	16	3	45	11.35
8	18	2.65	28	2.33
10	24	1.73	25	1.67
12	17	4.63	12	2
14	15	1.76	12	0.88

Figure 3. The consumption rate of *Ulva* germling blades by *Haliotis laevis* juveniles over 14 wk (no. of blades.abalone⁻¹.day⁻¹). Mean \pm std. error ($n = 3$).

Subsequently the diatom consumption did not correlate with either the *Ulva* germlings or the *U. lens* consumption, nor did it appear to relate to abalone growth.

During the feeding trial *N. jeffreyi* was reinoculated and the PVC plates rotated as illustrated in Table 4 and Figure 5. The consumption of diatoms corresponds to the plate rotation rather than to reinoculation. When comparing the two rotational profiles (1 = start at top – bottom – top and 2 = start at bottom – top – bottom) of diatom consumption they were shown to be statistically different ($t_{(df=41)} = -2.986$ [$P = 0.005$]). However, if the plates were not rotated then consumption was not significantly different. This indicates that rotating the plates had a considerable effect on the consumption of *N. jeffreyi*.

Two other species of diatoms, *Melosira cf. moniliformis* and *Synedra* sp. contaminated the *Ulva* germling treatment at various stages (Table 4). These diatoms were present throughout the 14 wk, however they only bloomed at the top of the plates on 3 separate occasions (start, week 11 and week 13). The contamination was quickly removed by physically detaching (hand abrasion) it from the substrate then siphoning the tanks' contents.

Figure 5. The consumption rate of *Navicula cf. jeffreyi* by *Haliotis laevis* juveniles over 14 wk (diatom cells.abalone⁻¹.day⁻¹). Mean \pm std. error ($n = 3$). The arrows at the top indicate plate rotation and the arrows at the bottom indicate inoculation.

Biochemical Composition of Algal Diets

The proximate biochemical composition of the *U. lens*/*N. jeffreyi* diet and *Ulva* germling diet can be seen in Table 5. The two diets both exhibit dry weights of approximately 12.5% with the *U. lens*/*N. jeffreyi* only slightly higher. Even though the lipid and carbohydrate components were greater in the *Ulva* germling diets the difference was not significant ($(F_{(df=1,15)} = 2.141$ [$P = 0.164$]) and $(F_{(df=1,14)} = 1.767$ [$P = 0.205$]) respectively). The protein level in the *Ulva* germling diet however was shown to be significantly higher ($(F_{(df=1,16)} = 10.893$ [$P = 0.005$])). The total extractable component (sum of protein, lipid and carbohydrate) was higher for the *Ulva* germlings diet.

DISCUSSION

The experimental juvenile macroalgae diet of *Ulva* germlings was comparable to the current commercial diet consisting of *Ulva lens* and *Navicula cf. jeffreyi* for the growth and survival of juvenile *Haliotis laevis*. The two diets demonstrated similar absolute and specific abalone growth rates but the *U. lens*/*N. jeffreyi* diet produced significantly larger abalone at the completion of the 14 wk feeding trial. Juveniles feeding on the *U. lens*/*N. jeffreyi* diet reached 10 mm (SL) in less than 13 wk whereas the *Ulva* germling diet produced juveniles of 9.61 mm (SL) at week

TABLE 4.

Diet	Dry Weight	Lipid	Protein	Carbohydrate
<i>Ulva</i> germling	12.44 (0.54)	7.12 (1.55)	32.30 (1.84)	43.86 (5.87)
<i>U. lens/N. jeffreyi</i>	12.82 (0.57)	4.37 (0.95)	24.17 (1.64)	35.85 (2.76)

14. Daume and Ryan (2004) found that for abalone of a similar initial size to the present trial (4 mm SL), it took less than 15 wk to reach 10 mm (SL) on just *U. lens* with a stocking density of approximately 50 animals per plate.

The transition at week 5, between the *Ulva* germling diet and *U. lens/N. jeffreyi* diet, producing significant larger abalone (Fig. 1) indicates that *Ulva* germlings were a more successful diet for *H. laevis* in the range of 3.5–6 mm. The failure to sustain a growth advantage to week 14 indicates better performance of the *U. lens/N. jeffreyi* diet for *H. laevis* in the range of 6–10 mm. The *Ulva* germling diet can therefore be considered an acceptable commercial diet for juvenile abalone (<6 mm) and used either as an alternative or in conjunction with the current commercial diet of *U. lens/N. jeffreyi*.

In the later phase of the trial, *Ulva* germlings were either no longer able to supply the juvenile abalone with specific nutrients or there was not enough biomass. Lack of biomass was an unlikely cause as only 25% of the *Ulva* germlings had been consumed at this point. To overcome either of these problems, freshly seeded plates could be cycled through to maintain a constant supply of new *Ulva* germlings. Daume et al. (2004) utilized this procedure for *U. lens*, which enabled the high initial growth rates of newly settled *Haliotis rubra* to be maintained for 114 d.

The abalone on the *Ulva* germling diet recorded 9 out of the last 10 weekly increases as not significant, which was further compounded by the reduction in abalone weekly growth to only 0.08 mm (SL) for the last 2 wk (Table 1). However the *U. lens/N. jeffreyi* diet also sustained a low weekly abalone growth rate of 0.24 mm (SL) for the last 2 wk. *H. rubra* has been shown to achieve steady growth for 100 d and then fail to grow further on some monospecific algal diets (Day & Fleming 1992).

The reduction of juvenile growth towards the end of the feeding trial occurred at the peak of the winter season with water temperatures dropping from 20.8°C to 19°C. The colder water temperatures may have resulted in the metabolic activity of the abalone reducing, causing less consumption of both algal diets and subsequently slower growth rates.

By week 12 both diets had produced abalone of approximately 9.5 mm (SL) with decreasing growth rates and at this stage could be weaned onto formulated feed (Dunstan et al. 2002, Fleming et al. 1996). However, it could be beneficial to maintain the abalone on its original diet for as long as possible by incorporating fresh seeded plates to reduce competition for food as well as the stress caused by handling (Daume et al. 2004, Fleming 1995).

An alternative to weaning may be to incorporate the *Ulva* germling diet as part of a mixed/rotational diet when it no longer supports adequate growth by itself (Day & Fleming 1992). The consumption of the subsequent algae, rotated through, may account for the deficiencies in the initial diet, in this case *Ulva* germlings (Simpson & Cook 1998). The plate method of feeding

juvenile abalone directs itself to diet rotation or a mixed diet plan whereby plates seeded with different diets can be interspersed throughout the tanks. Simpson and Cook (1998) and Stuart and Brown (1994) demonstrated that *Ulva* sp. as a singular diet produced the lowest abalone growth rates but when presented in a rotational/mixed diet it sustained excellent growth rates.

Growth rates of *H. laevis* fed the *Ulva* germling diet were not significantly different from those produced on the *U. lens/N. jeffreyi* diet (Table 2). The growth rate profile was similar to that obtained by Daume and Ryan (2004) utilizing *U. lens*, where once the first 2 wk had been removed, the next 6 wk recorded 84 $\mu\text{m}\cdot\text{day}^{-1}$ and the final 6 wk 63 $\mu\text{m}\cdot\text{day}^{-1}$. The growth rates during the first 2 wk were removed from Table 2 as any nutrient deficiency in a diet may be masked by the abalone ability to utilize its own energy stores (Fleming et al. 1996). As the juvenile abalone were taken off an *U. lens*/naturally occurring diatom diet, the weaning process was considered minimal compared with the recommendation of approximately 50 d (Day & Fleming 1992). However it was important to run the feeding trial for as long as possible to detect any effects of nutrient limitation and to determine the capacity of an alga to maintain acceptable abalone growth (Day & Fleming 1992).

The *Ulva* germling diet achieved growth rates of over 100 $\mu\text{m}\cdot\text{day}^{-1}$ during the first 6 wk. This was comparable to *Haliotis discus discus* growth rates attained over a month on a variety of macroalga germlings including *Colpomenia sinuosa*, *Ectocarpus siliculosus* and *Enteromorpha* sp. (Maesako et al. (1984) as cited in Kawamura et al. [1998]). Takami et al. (2003) showed that *Haliotis discus hannai* of approximately 1.8–2.2 mm and 2.8–2.9 mm shell length could reach growth rates of 80 and 100 $\mu\text{m}\cdot\text{day}^{-1}$ respectively on juvenile sporophytes of *Laminaria japonica*.

The specific growth rate reached over 1.3%.day⁻¹ and finished at 1%.day⁻¹ on both diets with no significant difference between them. The *Ulva* germling diet achieved 1.5%.day⁻¹ at week 4 but then exhibited a slow decline. Corazani and Illanes (1998) reported that *H. discus hannai* obtained a higher specific growth rate (0.69%.day⁻¹) utilizing adult *Ulva rigida* than other macroalgal diets, whereas *Haliotis rufescens* achieved the lowest specific growth rate. This was comparable to the 0.71%.day⁻¹ achieved by *H. discus hannai* on an *Ulva* sp. (Uki & Watanabe 1992). *Ulva lactuca* has been found to have reasonable dietary value for *Haliotis tuberculata* (1.16%.day⁻¹) but significantly lower for *H. discus hannai* (0.75%.day⁻¹) (Mai et al. 1996). *Haliotis iris* was only able to achieve 0.1%.day⁻¹ on *U. lactuca* (Stuart & Brown 1994). Simpson and Cook (1998) also found that the suitability of *Ulva* sp., as a feed was dependent on the abalone species.

The *Ulva* sp. being used in the present study was not manipulated through nutrient enrichment during the 14 wk feeding trial. Enriched *Ulva rigida* has been shown to produce growth rates of juvenile *Haliotis roei* comparable to those achieved on the best performing artificial diets (Boarder & Shpigel 2001). Taylor and Tsvetnenko (2004) showed that only 15 mgN.L⁻¹ enriched *U. rigida* produced significantly higher specific growth rates (0.28 $\mu\text{m}\cdot\text{day}^{-1}$) than unenriched *U. rigida*. Shpigel et al. (1999) reported growth rates of 44.47 and 121.47 $\mu\text{m}\cdot\text{day}^{-1}$ for *H. discus hannai* and *H. tuberculata* respectively on a high ammonia-N enriched *U. lactuca* compared with 31.7 and 80.72 $\mu\text{m}\cdot\text{day}^{-1}$ on low ammonia-N enriched *U. lactuca*.

The growth rate for *H. tuberculata* produced on the high-enriched *U. lactuca* (Shpigel et al. 1999) was the only growth rate to exceed that obtained on the *Ulva* germling diet in this study.

During the culturing process, before the feeding trial began, the *Ulva* germings were grown in f/2 media (minus the PII metals, sodium metasilicate and vitamin stock solutions) (Guillard & Ryther 1962). The elevation in nutrients at the start may have led to the extremely high level of consumption (week 3, Fig. 3) resulting in the significantly larger abalone size during the first 5 wk and in turn the rapid $1.5\% \cdot \text{day}^{-1}$ specific growth rate. Therefore it is important to investigate the benefit of culturing nutrient enriched (high ammonia-N seawater) *Ulva* germings to achieve the best juvenile abalone growth rates.

The consumption rate of *Ulva* germings was extremely high during the first month and subsequently the abalone grew rapidly. However, once the consumption rate reduced so did the growth rates giving a significant correlation (Fig. 3). Hone (1992) showed that *Ulva australis* was rapidly consumed by abalone. On a quantitative basis *Ulva* sp. had the lowest consumption in $\text{g} \cdot \text{abalone}^{-1} \cdot \text{day}^{-1}$ compared with five other adult macroalgae and subsequently produced the lowest growth rates for *Haliotis midae* (Simpson & Cook 1998). Boarder and Shpigel (2001) reported that inorganically enriched *U. rigida* had the lowest consumption rate but was still able to produce growth rates of *H. roei* comparable to that achieved on some of the best artificial diets. As mentioned before, ammonia-N enriched *U. lactuca* produced the highest growth rates for both *H. discus hannai* and *H. tuberculata* but these rates were recorded while consuming significantly less biomass (Shpigel et al. 1999). This indicates that nutrient enriched *Ulva* sp. produces greater growth rates, while requiring less biomass to achieve them.

Daume and Ryan (2004) reported that at the start of a feeding trial *U. lens* had 55% coverage and decreased until 11% was left at 9 wk, when new plates were introduced. That consumption pattern is considerably faster than recorded in this study with 14 wk needed to achieve approximately 11% cover from a similar start value. The different stocking density accounts for the difference in *U. lens* consumption rates with the present study starting approximately 20 fewer animals per plate (Daume & Ryan 2004).

The *U. lens* consumption was significantly correlated with the *Ulva* germling consumption indicating that the juvenile abalone exhibited a similar preference for the two species of green algae (Fig. 4). This is understandable because the biochemical profiles of the two diets were fairly similar (Table 5). The dry weight of both diets, even though similar (12.5%), was lower than $\approx 15\%$ expected for the majority of algae such as *Ulva* sp. (Mercer et al. 1993, Shpigel et al. 1999). This may be caused by the sampling method incorporating all the biofilm/moisture from the plates rather than just the two green algae.

The *Ulva* germling diet exhibited a higher overall percentage extracted, possibly because of the high ash content of diatoms including *Navicula* (Brown & Jeffrey 1995). The individual biochemical components were also higher. Specifically, the protein level (32.3%) which was significantly larger than that of the *U. lens/N. jeffreyi* diet. It was nearly identical to that of *U. rigida* when enriched from 11.4% to 32.2% protein by using high nutrient water ($5 \text{ g} \cdot \text{N} \cdot \text{m}^{-2} \cdot \text{day}^{-1}$; $0.6 \text{ g} \cdot \text{P} \cdot \text{m}^{-2} \cdot \text{day}^{-1}$) (Boarder & Shpigel 2001). The *Ulva* germings as a 3-dimensional juvenile macroalgae are in a phase of high growth and therefore may be able to utilize the limited nutrient supply in the water extremely well compared to what the 2-dimensional *U. lens/N. jeffreyi* diet can.

The total percentage extracted ($\approx 65\%$) from the *U. lens/N. jeffreyi* diet may have been reduced because of the combination of microalgae present within the diet. Brown and Jeffrey (1995) ex-

tracted only 56% from *N. jeffreyi* with protein as the major constituent and carbohydrate the lowest, whereas 12% lipid, 28% protein and 7% carbohydrate have been extracted for a combination of diatoms (Brown et al. 1997). The biochemical composition can vary considerably between diatom species let alone a diet containing *U. lens*, diatoms and biofilm components (Brown 1991, Brown et al. 1997, Lewin & Guillard 1963).

Importantly the lower level of lipid, protein and carbohydrate present within the *U. lens/N. jeffreyi* diet produced significantly larger abalone at the end of the 14 wk feeding trial. Therefore the higher amounts of the biochemical components do not increase growth but rather an optimal level may be responsible. Lipid levels of 4% to 5% have been shown to be optimal for abalone, which corresponds with the *U. lens/N. jeffreyi* diet, whereas the *Ulva* germling diet was higher (Dunstan et al. 2000, Uki & Watanabe 1992). High levels ($\geq 5\%$) of dietary lipid have been shown to be detrimental to abalone growth and are believed to depress the digestibility of other nutrients (Britz & Hecht 1997, Uki & Watanabe 1992, Van Barneveld et al. 1998). Therefore the high lipid level present in the *Ulva* germling diet may have restricted the optimal growth rates obtained in the first month of the trial.

Optimal protein levels of 28% have been reported but can range from 20% to 35% depending on abalone species (Britz & Hecht 1997, Coote et al. 2000, Mai et al. 1995, Uki & Watanabe 1992, Vandepeer & Van Barneveld 2002). However to maximize protein utilization not only should the diet contain sufficient readily digestible protein but a well balanced mixture of essential and non-essential amino acids (Britz & Hecht 1997, Mai et al. 1995). Therefore the *U. lens/N. jeffreyi* diet may provide biochemical components closer to the optimal levels for juvenile *H. laevigata* because it produced larger individuals.

The *N. jeffreyi* consumption (Fig. 5) did not correlate with either of the algae species nor any of the abalone results. Weeks 7–10 and 12 all produced negative consumption indicating that the *N. jeffreyi* was reproducing faster than the abalone could consume it. The consumption rate of *N. jeffreyi* did not correspond with the reinoculation but rather the plate rotation 180° about the horizontal.

This can be accounted for by two reasons; firstly because the light gradient through the tanks allowed *N. jeffreyi* situated at the top to receive greater light intensity inducing faster growth and secondly because changes in grazing pressure caused by light sensitivity/migration of abalone. These notions were substantiated through visual observation during the trial because diatom counts increased when at the top and juvenile abalone were found on the bottom of the tanks during the day. Positive relationships between feed intake and the duration of darkness have been shown by Dixon (1992) and Fleming et al. (1996), hence, when the juvenile abalone migrate from the bottom to feed high density of diatoms are closer reducing the effort expended to graze. Daume et al. (2004) indicated that the light intensity tended to be higher at the top of plates and migration to the bottom of the tank was evident.

When the plates were rotated at week 3 the high *N. jeffreyi* densities at the top were transferred to the bottom. This caused the high densities to be closer to the majority of abalone and subsequently caused a spike in consumption (Fig. 5). *N. jeffreyi* consumption dropped as the density at the bottom declined, whereas the density increased at the top because of greater light intensity and less grazing pressure. At week 7 the consumption became negative because the growth at the top exceeded the consumption at the bottom. Once the second rotation at week 10 was performed

the consumption began to increase again as the high *N. jeffreyi* density was available to the juvenile abalone at the bottom. The two rotational profiles (i.e., top-bottom-top vs. bottom-top-bottom) were shown to be significantly different. Therefore it would be beneficial to rotate diatom-cultured plates at least weekly to maintain high diatom densities at the bottom where the majority of abalone reside.

The contaminating diatom species only occurred in the *Ulva* germling diet tanks indicating that it was present from the creation of the diet. It was not determined if the juvenile abalone utilized these contaminating diatoms as a food source although *Synedra* sp. was probably of a suitable size. It may have been difficult for the juveniles to deal with the *Melosira* cf. *moniliformis* because along with its large cell size it proceeded to rapidly form into dense mats with chains exceeding 5 cm in length. The large blooms of *M. moniliformis* occurring at week 11 and 13 may have had some impact on the declining growth rates because the juveniles are susceptible to smothering and entanglement (Daume et al. 2004).

Ulva germlings are a suitable feed for juvenile *H. laevigata* because they produced comparable absolute and specific growth rates to the *Ulvella lens* and *Navicula* cf. *jeffreyi* diet currently used in commercial aquaculture. Further investigation into the theoretical and procedural principles behind the development of the *Ulva* germling diet could allow for the diet to incorporate a variety of different algal species.

ACKNOWLEDGMENTS

The authors thank Fiona Graham, Sam Hair and William Strong for their assistance in material collection and routine measurements; Challenger TAFE for the space to run the feeding trial and Great Southern Marine Hatcheries for supplying the juvenile greenlip abalone. This study was funded as part of an FRDC project (2002/203) and conducted as part of a PhD by the first author.

ABSTRACT This study reports growth rates estimates for *Hexaplex (Trunculariopsis) trunculus* (Gastropoda: Muricidae) from mark/recapture experiments carried out in the Ria Formosa lagoon (Algarve coast, southern Portugal). A total of 726 specimens (shell length and total weight ranging between 20.65–58.36 mm and 0.86–19.89 g, respectively) were marked with Dymo tape tags and released into a fish culture earth pond. During the marking process, no adverse effects on the whelks' health and behavior or immediate postmarking mortality were detected. Periodical recapture operations were undertaken using a traditional fishing gear designated locally as "wallet-line" and by hand gathering by scuba divers. A total of 170 whelks were caught, with a total of 216 recaptures (shell length and total weight ranging between 36.22–65.97 mm and 4.42–27.35 g, respectively), thus corresponding to a recapture rate of 29.8%. Despite the loss of one tag, all remaining tags were intact and easily readable. Marked individuals presented low monthly growth rates, in terms of shell length (1.0 mm/month or 2.3%/month), shell perimeter (2.0 mm/month or 3.1%/month) and total weight (0.7 g/month or 10.8%/month), which were highly variable between individuals and higher in smaller specimens. Data were used to estimate the von Bertalanffy growth parameters (length and weight) ($K=0.41$, $L_{\infty}=82.76$, $W_{\infty}=49.97$ and $t_0=-0.05$). The growth rate of *T. trunculus* was compared with results obtained in similar studies with other gastropod species to evaluate its potential for molluscan aquaculture.

KEY WORDS: *Hexaplex (Trunculariopsis) trunculus*, Gastropoda, Muricidae, mark/recapture, growth rate

INTRODUCTION

Marking methods have been readily applied to several species of gastropods, mainly because of the presence of an external shell on which marks or tags can be attached with little or no adverse effects to the animals (Jones 1979, Gosselin 1993). Such experiments with gastropods have been used in diverse types of studies, to assess movement (Eversole & Anderson 1988, Himmelman 1988), fishing rate (Hancock 1963), field of attraction and effective fishing area of baited traps (Himmelman 1988, McQuinn et al. 1988, Sainte-Marie 1991), species' behavior towards baited traps (Ito et al. 1980), population size and mortality (Hancock 1963) and growth rate (Hancock 1963, Eversole & Anderson 1988).

Various marking techniques have been used in gastropods, such as painting the shell spire with quick drying paints (Hancock & Urquhart 1959, Hancock 1963, Jones 1979, Ito et al. 1980), applying color coded nail polish to the shell (Laxton 1970, Gosselin 1993), attaching rubber bands or nylon lines with tags around the shell (Appeldoorn 1988, Himmelman 1988, McQuinn et al. 1988, Sainte-Marie 1991), gluing a variety of tags to the shell (Hancock & Urquhart 1959, Smith 1987, Eversole & Anderson 1988, Amos & Purcell 2003), scrubbing the shell lip free from the periostracal layer (Hancock & Urquhart 1959, Hancock 1963), drilling and wiring the shell (Laxton 1970, Weil & Laughlin 1984, Kideys & Nash 1993, Kideys 1994), chemically marking the shell and operculum with fluorescent dyes (Kideys & Nash 1993) and using underwater metal detectors to recapture specimens marked with aluminum tags (Crowe et al. 2001).

The muricid gastropod *Hexaplex (Trunculariopsis) trunculus* (Linnaeus, 1758) is a common inhabitant of the subtidal and in-

tertidal areas of the Ria Formosa lagoon (Algarve coast, southern Portugal), where it is subjected to a locally important artisanal fishery. This activity is traditionally undertaken both by manual harvesting during low tide and with an illegal and artisanal fishing gear known as "wallet-line," but more recently this species has also been caught by scuba divers operating illegally inside the lagoon. Furthermore, because of a growing demand for gastropods in the seafood market, the commercial value of *T. trunculus* in Portugal has increased markedly in recent years (reaching prices of €10 – 15/kg for first sale), which has been generating high expectations in terms of its potential as a new species for molluscan aquaculture.

Integrated in a general study on the biology, ecology and fishery of *T. trunculus* in the Ria Formosa lagoon, this work aimed to assess the growth rate of this species by mark/recapture experiments in a fish culture earth pond. To the authors' knowledge, this was the first experiment of this kind ever made with *T. trunculus* and the first growth data (growth rates and growth parameters) available for this species. Moreover, the information gathered in this study will be most useful for assessing the potential of *T. trunculus* for molluscan aquaculture, as well as for establishing adequate management measures for this artisanal fishery.

MATERIALS AND METHODS

Mark/Recapture Experiments

Marking experiments were carried out with commercial samples of *T. trunculus* from the Ria Formosa lagoon (Algarve coast, southern Portugal). Prior to marking, colonizing algae and/or encrusting organisms (mainly polychaetes) were removed from the shell with a hard brush and a small area of the largest whorl of the shell was carefully smoothed with sandstone and clean dried

*Corresponding author. E-mail: pvasconcelos@cripsul.ipimar.pt

with absorbent paper. Subsequently, the specimens were tagged with Dymo tape with two alphanumeric characters. The margins of these tags were cut with scissors, ensuring a tag of $\approx 6 \times 4$ mm size and facilitating adherence to the rounded and irregular surface of the gastropod shell. The tags were fixed with cyanoacrylate glue and covered with epoxy glue (Fig. 1A), to diminish abrasion of the tag caused by the burrowing movements of the whelks into the sediment and the settlement of encrusting organisms over the tags, which could jeopardize mark retention and readability. The tags were generally fixed between the two most recently deposited growth bands of the last whorl of the shell (Fig. 1A), to prevent eventual dropping of excessive glue from the shell onto the soft body of the gastropods. Finally, after allowing the glue to dry for approximately half hour, marked individuals were rinsed in seawater to avoid potential contamination problems provoked by glue residues, and maintained overnight in an aquarium with running seawater, where they were examined for general condition (comparison of behavior between marked and unmarked specimens).

Mark/recapture experiments were undertaken in a fish culture earth pond of the Olhão fish culture experimental station, which was previously limited by a plastic net fence (area ≈ 100 m²; maximum depth ≈ 2 m). This earth pond receives water directly from the adjacent Ria Formosa lagoon and closely resembles the surrounding natural environment in terms of sediment type, water quality and food availability. Seawater temperature and dissolved oxygen in the earth pond were monitored daily with a multi parameter monitor (Yellow Springs Incorporated, YSI 6820). Periodic recaptures were undertaken monthly, using a traditional fishing gear designated locally as "wallet-line" baited with cockles (*Cerastoderma edule*) and by hand gathering by scuba divers (whenever water visibility allowed for diving recapture operations).

During the marking process and immediately after the recapture operations, specimens were measured for shell length (SL-mm) (Fig. 1B) with a digital calliper (MITUTOYO Digimatic: CD-15D; precision = 0.01 mm), shell perimeter (SP-mm) of the last whorl of the shell (Fig. 1B) and weighed for total weight (TW-g) on a top loading digital balance (AND: HF-2000 G; precision = 0.01 g). Particular care was taken to drain as much water as possible from the mantle cavity before weighing. On both occasions, the position of the tag on the gastropod shell was also registered to verify the degree of shell deposition (tag position at recapture versus tag position at marking) (Fig. 1C).

Estimation of Growth Rates

Monthly growth rates in terms of unit/month and percentage/month (mm and %SL/month, mm and %SP/month, g and %TW/month, no. and %growth bands/month) were estimated with the following equations:

$$GR = \frac{(S_r - S_m)}{(t_r - t_m)} * 30 \quad \text{and} \quad \%GR = \frac{GR}{S_m} * 100$$

where: GR is the monthly growth rate (unit/month); %GR is the monthly growth rate (%/month); S_r is the size at recapture (SL-mm, SP-mm, TW-g or tag position); S_m is the size at marking (SL-mm, SP-mm; TW-g or tag position); t_r is the day of recapture; and t_m is the day of marking.

In the case of multiple recaptures, the size increment used (length, perimeter, weight and tag position) was derived from initial size and last recapture.

The relationships between the individuals' size (shell length at marking process, grouped in 5 mm SL classes) and the respective monthly growth rates (unit/month and percentage/month) were assessed by regression analysis (least squares method) and the degrees of association between variables were estimated by the correlation coefficient (r).

Estimation of Growth Parameters

Whenever the period at liberty (interval between marking and recapture) is small, growth rates may be related to the mean length between marking and recapture ($(S_m + S_r)/2$), using the Gulland-Holt plot (Gulland & Holt 1959). Because the present mark/recapture data lacked small individuals (<20 mm SL), data on growth rates of individuals hatched at the end of June 2004 in the Tavira molluscan aquaculture experimental station were pooled with data on growth rates obtained in mark/recapture experiments. Data were converted into weekly growth rates to increase the number of points in the plot and thus enhance the accuracy of this graphical method. Additionally, recaptured individuals that did not grow during the study period were removed from this estimation of growth parameters.

Growth parameters (K and L_∞) were estimated from the Gulland-Holt plot by the following relations (Gulland & Holt 1959):

$$K = -b \quad \text{and} \quad L_\infty = \frac{-a}{b}$$

where: K is the growth coefficient; L_∞ is the asymptotic shell

Figure 1. A, *Hexaplex (Trunculariopsis) trunculus* marked with a Dymo tape tag (circle); B, Schematic representation of the shell length (SL-mm) and shell perimeter (SP-mm) measurements; C, Location of the shell growth bands (arrows); D, *T. trunculus* recaptured with a recently deposited growth band (arrows); (scale bar = 10 mm).

length (SL-mm); a is the linear regression intercept on the Y-axis; and b is the linear regression slope.

The theoretical age at shell length zero (t_0) cannot be obtained from mark/recapture data alone (without specific size-at-age information). For the present purposes t_0 was assumed to correspond to the shell length of *T. trunculus* at hatching ($L_r = 1.64 \pm 0.22$ mm SL, $n = 100$) (Vasconcelos et al. 2004a) and was calculated from the following expression (von Bertalanffy 1938):

$$t_0 = t + \frac{1}{K} \ln \frac{(L_\infty - L_r)}{L_\infty}$$

Subsequently, shell growth of *T. trunculus* was modeled by applying all these growth parameters (K , L_∞ and t_0) in the von Bertalanffy growth in length function, expressed by the following equation (von Bertalanffy 1938):

$$L_t = L_\infty [1 - e^{-K(t-t_0)}]$$

where: L_t is the shell length at age t (SL-mm); L_∞ is the maximum asymptotic shell length (SL-mm); K is the von Bertalanffy growth coefficient; and t_0 is the theoretical age at shell length zero (years).

After applying the value estimated for maximum asymptotic shell length (L_∞) in the weight/length relationship ($TW = a * SL^b$) for this species, the maximum asymptotic total weight (W_∞) was obtained. Finally, growth in total weight of *T. trunculus* was modeled by the von Bertalanffy growth in weight function, by using the following expression (von Bertalanffy 1938):

$$W_t = W_\infty [1 - e^{-K(t-t_0)^n}]$$

where: W_t is the total weight at age t (TW-g); W_∞ is the maximum asymptotic total weight (TW-g); K is the von Bertalanffy growth coefficient; t_0 is the theoretical age at total weight zero (years); and n is the slope (b) of the weight/length relationship ($TW = a * SL^b$).

RESULTS

Mark/Recapture Experiments

A total of 726 whelks were marked and released between March 2003 and June 2004. These marked specimens had an average shell length of 44.32 ± 5.34 mm and average total weight of 8.94 ± 3.06 g (ranges 20.65–58.36 mm and 0.86–19.89 g, respectively). A careful inspection of the condition of marked individuals held in the aquarium did not reveal any adverse effects on the gastropods health and behavior or immediate postmarking mortality.

Daily monitoring of temperature and dissolved O_2 in the earth pond (Fig. 2) showed that the average temperature was relatively high ($20.7 \pm 4.9^\circ\text{C}$), varying between a minimum of 11.0°C in December 2003 and a maximum of 29.4°C in August 2003. The average dissolved O_2 was 7.2 ± 1.1 mg/L, showing an opposite trend relative to water temperature, with a maximum in May 2004

Figure 2. Seawater temperature and dissolved oxygen in the earth pond where the marked specimens of *Hexaplex (Trunculariopsis) trunculus* were released.

(11.4 mg/L) and an unexpected minimum in February 2004 (4.2 mg/L).

In the mark/recapture study, 170 whelks were caught (216 recaptures) with an average shell length of 49.36 ± 4.92 mm and average total weight of 11.89 ± 4.08 g (ranges 36.22–65.97 mm and 4.42–27.35 g, respectively). Overall, these 216 recaptures corresponded to a recapture rate of 29.8%. In this context, it is worth emphasizing that most recaptures were caught only once (133 individuals = 78.2%), 30 whelks were recaptured twice (17.7%), six were caught three times (3.5%), and one was recaptured four times (0.6%). In all, 107 dead whelks were recovered from the earth pond during diving operations, corresponding to a mortality rate of 14.7%. After 16 mo from the beginning of the study, only one specimen was recaptured without a tag. All other recaptured specimens had their tags intact and easily readable, most of them presenting recently deposited growth bands (Fig. 1D).

Estimation of Growth Rates

The recaptured whelks presented average monthly growth rates of 1.0 ± 1.0 mm SL ($2.3 \pm 2.6\%$ SL/month), 2.0 ± 1.6 mm SP ($3.1 \pm 2.8\%$ SP/month) and 0.7 ± 0.6 g TW ($10.8 \pm 11.3\%$ TW/month). However, growth rates were highly variable among individuals, with some whelks simply not growing (in terms of shell length, shell perimeter and/or total weight), whereas the fastest growing specimens exhibited much higher growth rates i.e., 4.0 mm SL/month (13.4% SL/month), 7.4 mm SP/month (15.7% SP/month) or 3.4 g TW/month (59.0% TW/month) (Table 1).

Individually, growth rates varied with size (initial shell length), being highly variable between individuals, and generally higher in smaller than in larger individuals. In fact, individual monthly growth rates displayed a decreasing trend during ontogeny, a phenomenon that was more evident in the relationships between growth in shell length, shell perimeter and shell deposition as a function of shell length (Figs. 3A, B, C, D, G, H), than in the rela-

TABLE 1.

Monthly growth rates (shell length, shell perimeter and total weight) of the *Hexaplex (Trunculariopsis) trunculus* specimens recaptured in the earth pond.

tionships between growth in total weight in function of shell length (Figs. 3E, F).

Because of the high interindividual variability observed in monthly growth rates, individual data were grouped in size classes (5 mm SL) and subjected to regression analyses (Fig. 4). After pooling data into size classes, the inverse relationship between size (shell length at marking) and growth rates became even more evident, further strengthening the decreasing trend in growth during ontogeny. This was particularly evident in the relationships SL/month in function of shell length (Figs. 4A, B) and SP/month in function of shell length (Figs. 4C, D), whereas the relationships TW/month in function of shell length (Figs. 4E, F) presented poorer fittings. Furthermore, the relationships established between shell deposition rate (growth bands/month) and shell length (Figs. 4G, H) perfectly illustrate the remarkable decline in shell deposition with specimen size (i.e., during growth), reflected by the high correlation coefficients (r) registered in these regressions.

Estimation of Growth Parameters

The Gulland-Holt plot of weekly growth rate versus mean shell length (with pooled data from mark/recaptured gastropods and from laboratory hatched gastropods) is illustrated in Figure 5A. After applying this graphical method, the estimated growth param-

eters were $K = 0.008/\text{wk}$ (0.41/y) and $L_{\infty} = 82.76$ mm SL. The calculation of t_0 , assuming the shell length of *T. trunculus* at hatching of $L_t = 1.64$ mm SL, produced a value of -0.05 y. The von Bertalanffy growth function for *T. trunculus* in terms of shell length ($L_t = 82.76[1 - e^{-0.41(t+0.05)}]$) is presented in Figure 5B.

After employing the weight-length relationship ($TW = 0.00008SL^{3.022}$; $n = 2401$; $r = 0.975$; $P < 0.05$) estimated by Vasconcelos et al. (2004b) for *T. trunculus* from the Ria Formosa lagoon (Fig. 5C), the von Bertalanffy growth function for this species in terms of total weight ($W_t = 49.97[1 - e^{-0.41(t+0.05)}]^{3.022}$) was obtained (Fig. 5D).

DISCUSSION

Mark/Recapture Experiments

Marked gastropods are frequently disturbed and stressed by tagging procedures (Himmelman 1988) that may result in quite different behavior from undisturbed specimens (Sainte-Marie 1991), often exhibiting a period of stress-induced inactivity during release after extended tagging manipulations (McQuinn et al. 1988). In this study, the marking process had no detectable adverse effects on the marked whelks' health and behavior. When returned to the aquarium, marked whelks soon started crawling (within a

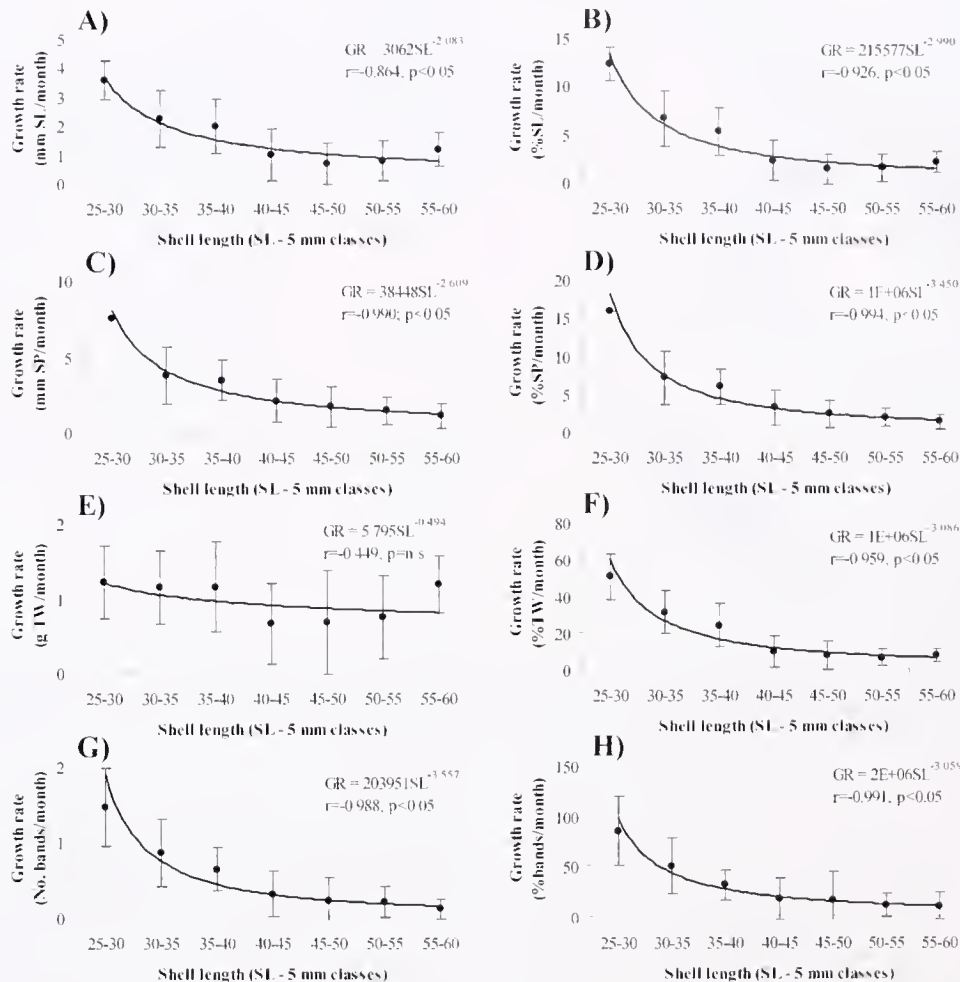

Figure 4. Monthly growth rates of recaptured specimens of *Hexaplex (Trunculariopsis) trunculus* (grouped in 5 mm SL classes) in terms of shell length, shell perimeter, total weight and shell deposition: A, SL/month; B, %SL/month; C, SP/month; D, %SP/month; E, TW/month; F, %TW/month; G, no. growth bands/month; H, % growth bands/month.

maximum of 5–10 min), and no behavioral differences were apparent between marked and unmarked individuals. This was probably because *T. trunculus* quickly withdraws into the shell when removed from seawater, preserving most of the inner moisture.

The recapture rate obtained during these experiments (29.8%) was low, considering that specimens were released inside a fenced area on an earth pond, virtually without potential predators. In this case, the high proportion of uncaught individuals might have been because of the type of bottom in the earth pond (muddy sediment), which favored the burrowing movements of *T. trunculus* and decreased underwater visibility during recapture operations by hand gathering by scuba divers.

An unexpectedly high mortality rate was registered (14.7%). Besides natural mortality, this might have been caused by other circumstances, namely a possible weakness and fragility of some marked individuals. Indeed, the fact that specimens were obtained from commercial samples meant that neither date of capture nor the conditions under which captured whelks were held were known. Additionally, despite water temperature in the earth pond closely reflecting the environmental conditions in the adjacent Ria Formosa lagoon, dissolved oxygen was low during some periods

and might have also contributed to the mortality of marked specimens.

However, this high mortality rate is probably slightly underestimated, because dead individuals could only be recovered from the earth pond bottom by diving, frequently in poor visibility. Moreover, the burrowing behavior of *T. trunculus*, coupled with the high sedimentation rate inside the earth pond, might have also made difficult the detection of all dead specimens, thus probably contributing to an underestimation of total mortality rate.

Estimation of Growth Rates

The monthly growth rates estimated in this study, in terms of shell length (1.0 mm/month or 2.3%/month), shell perimeter (2.0 mm/month or 3.1%/month) and total weight (0.7 g/month or 10.8%/month) were considered somewhat low, taking into consideration that *T. trunculus* is supposed to be a species with a short/medium life-span. Nevertheless, this growth rate is common among muricid species, because according to Spight et al. (1974) a typical young muricid grows only 1–2 mm/month. As expected, monthly growth rates decreased markedly during ontogeny, with smaller specimens growing more rapidly than larger ones. This was particularly evident in growth in terms of shell length, shell

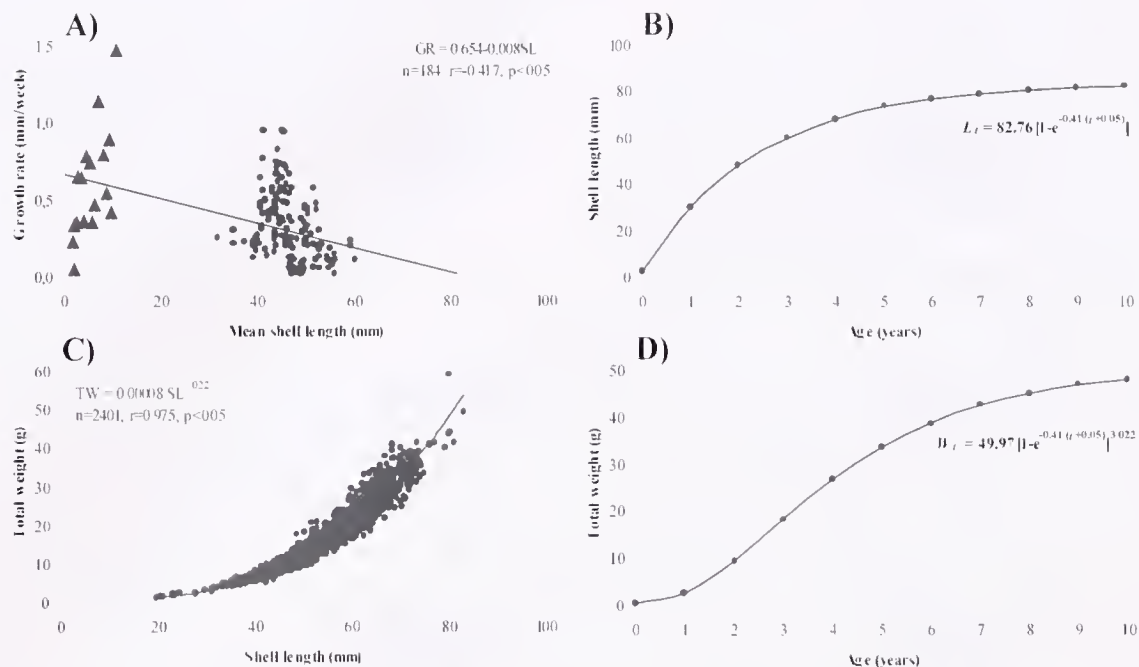

Figure 5. A, Gulland-Holt plot of weekly growth rate versus mean shell length for *Hexaplex (Trunculariopsis) trunculus* (● data from marked/recaptured gastropods, ▲ data from laboratory hatched gastropods); B, von Bertalanffy growth function in terms of shell length for *T. trunculus*; C, weight-length relationship for *T. trunculus* (data from Vasconcelos et al. 2004b); D, von Bertalanffy growth function in terms of total weight for *T. trunculus*.

perimeter and shell deposition rates, but less noticeable in terms of total weight growth rate. This phenomenon was probably influenced by the seasonal fluctuations in physiological condition and total weight normally associated with the reproductive cycle of the species, being accentuated by the fact that it was virtually impossible to assure the complete removal of water from the shells, thus contributing to some variability in weighing both at marking and recapture operations.

Moreover, monthly growth rates were highly variable among individuals and some whelks did not grow between marking and recapture. The same high interindividual variability in growth rates has been noted in several gastropod species and has been attributed to diverse factors (e.g., Tallmark 1980, Smith 1987 and references therein). In fact, most muricid adults simply do not grow (Spight et al. 1974), and in some experiments with different species, larger specimens (presumably adults) did not grow at all during the study period, after becoming reproductively active, even though they were substantially smaller than their maximum shell length (e.g., Hancock 1959, Laxton 1970, Fotheringham 1971, Spight et al. 1974, Tallmark 1980, Appeldoorn 1988). However, in the present case, despite reduction or even cessation of growth in shell length, *T. trunculus* continued slowly growing in shell perimeter, total weight and shell deposition, with monthly growth rates that were invariably higher than shell length growth rates.

However, these growth estimates are most likely underestimated, because despite the inclusion of some juveniles in the experiments, marked and recaptured gastropods were dominated by adult specimens (consequently with a much lower growth rate), which obviously induced a significant underestimation of the overall growth rate of the species. Furthermore, notwithstanding the use of a non size-selective fishing gear in the recapture operations, the samples caught through snorkeling and scuba diving could be size-biased, because bigger whelks were more conspicuous and

more easily detected than smaller individuals, especially in a burrowing species and under low water visibility conditions. In addition, many animals were recaptured less than 1 year after being marked and during winter and spring, when lower water temperatures and less food availability in the earth-pond might have slowed their metabolism and decreased growth rates. For all these reasons, the present growth rates of *T. trunculus* should be interpreted with some caution and considered as average values for the size range used in this study (dominated by adults). Extrapolation of the data to juveniles is especially problematic. *T. trunculus* individuals hatched at the end of June 2004 and maintained until now in the Tavira molluscan aquaculture experimental station presented a much higher growth rate, hatching with 1.64 ± 0.22 mm SL and reaching 11.66 ± 2.05 mm SL after 4 mo (end of October 2004), therefore corresponding to a monthly growth rate of 2.5 mm SL/month during the first 4 mo of life (Vasconcelos et al. 2004a).

The comparison of the growth rates of *T. trunculus* obtained in this study with those obtained for other gastropod species (namely some muricids with high commercial value) was difficult, because most studies had different objectives, different experimental designs (e.g., field vs. laboratory, with vs. without additional food supply) and variable size ranges of the individuals used for growth rate estimations (e.g., juveniles vs. adults) (Table 2). The average monthly growth rate of *T. trunculus* (1.0 mm/month) compared favorably with those obtained for *Ocenebra lurida*, *Urosalpinx cinerea*, *Busycon carica* and *Turbo sarmaticus*, being equal to other growth rates estimated for *B. carica*, *Busycon canaliculatum* and *Ocenebra interfossa*. In contrast, the present growth rate was lower than those obtained for *B. carica*, *Cerastostoma foliatum* and *Cerithium nodulosum* and much lower than the growth rates of *Ocenebra lumaria*, *Eupleura caudata*, *Bolinus brandaris*, *Concholepas concholepas*, *Chicoreus virgineus*, *Strombus gigas* and *Chicoreus ramosus*. In this context, it is worth emphasizing that

TABLE 2.

Comparison of the growth rate of *Hexaplex (Trunculariopsis) trunculus* obtained through mark/recapture experiments with growth rates reported for other gastropod species.

Species	Location	Size range (SL-mm)	Growth rate (SL-mm)	Author(s)
<i>Hexaplex trunculus</i>	Ria Formosa, Portugal	20–58 mm	1.0 mm/month	*present study
<i>Ocenebra lurida</i>	Washington, U.S.A.	12–22 mm	0.4 mm/month	Spight et al. (1974)
<i>Busycon canaliculatum</i>	South Carolina, U.S.A.	—	1.0 mm/month	Eversole and Anderson (1988)
<i>Busycon carica</i>	South Carolina, U.S.A.	—	1.0 mm/month	Eversole and Anderson (1988)
<i>Ocenebra interfossa</i>	Washington, U.S.A.	12–21 mm	1.0 mm/month	Spight et al. (1974)
<i>Ceratostoma foliatum</i>	Washington, U.S.A.	juveniles	<2.0 mm/month	Spight et al. (1974)
<i>Cerithium nodulosum</i>	Guam, Mariana Islands	25–75 mm (juveniles)	2.3–4.6 mm/month	Yamaguchi (1977)
<i>Ocenebra lumaria</i>	Asamushi, Japan	—	3.7 mm/month	Luckens (1970)
<i>Eupleura caudata</i>	Virginia, U.S.A.	—	4.0 mm/month	Mackenzie (1961)
<i>Bolinus brandaris</i>	Catalonia, Spain	>5 mm (juveniles)	4.3 mm/month	Ramón and Flos (2001)
<i>Concholepas concholep</i>	Chile	juveniles	4.7 mm/month	Lara and Montes (1988)
<i>Chicoreus virgineus</i>	Cuddalore, India	70–85 mm	3.0–5.0 mm/month	Ramesh et al. (1992)
<i>Strombus gigas</i>	Los Roque, Venezuela	30–190 mm	4.0–15.0 mm/month	Weil and Laughlin (1984)
<i>Chicoreus ramosus</i>	Phuket, Thailand	25–45 mm (juveniles)	11.4 mm/month	Bech (1992)
<i>Urosalpinx cinerea</i>	England, U.K.	juveniles	3.0 mm/year	Hancock (1959)
<i>Busycon carica</i>	North Carolina, U.S.A.	juveniles	10.2 mm/year	Magalhães (1948)
<i>Turbo sarmaticus</i>	Port Alfred, South Africa	42 mm (juveniles)	2.4–13.8 mm/year	Foster et al. (1999)
<i>Busycon carica</i>	Virginia, U.S.A.	juveniles	13.2 mm/year	Kraeuter et al. (1989)

most of these studies used newly hatched specimens or small juveniles during growth studies, thus growth rates are presumably overestimated considering the overall size ranges (juveniles + adults) of the natural populations of these species. Moreover, some of these species have a maximum size much bigger than *T. trunculus*. Comparisons of growth rates (mm SL/month) between gastropod species are complicated and should be carefully interpreted.

Estimation of Growth Parameters

The von Bertalanffy growth function in terms of shell length estimated for *T. trunculus* ($L_t = 82.76[1 - e^{-0.41(t+0.05)}]$) further confirmed that the growth of this gastropod species is relatively slow ($K = 0.41$). According to these data the minimum landing size of *T. trunculus* (MLS = 50 mm SL) is only attained at 2.20 y old. Furthermore, at 95% of its theoretical maximum shell length (95% $L_\infty = 82.76$ mm), the von Bertalanffy growth equation yielded an estimated age of 7.24 y for *T. trunculus*, which can be considered a relatively short/medium life span for a gastropod species.

The estimated maximum asymptotic shell length ($L_\infty = 82.76$ mm) closely approached the maximum size attained locally by *T. trunculus*. During a general study on the biology, ecology and fishery of this species in the Ria Formosa lagoon, the largest specimen sampled measured 82.84 mm. Nevertheless, specimens of this size were exceptional, because among 2484 *T. trunculus* measured during a 1-y sampling program, only one individual was bigger than the asymptotic shell length estimated in this study ($L_\infty = 82.76$ mm), which was very similar to the maximum size attained by this species in the Ria Formosa lagoon (85 mm SL) (Muzavor & Morenito 1999) and included in the maximum size range reported for *T. trunculus* by other authors, between 80 mm SL (Pope & Goto 1991) and 90 mm SL (Macedo et al. 1999).

The von Bertalanffy growth function in terms of total weight estimated for *T. trunculus* ($W_t = 49.97[1 - e^{-0.41(t+0.05)}]^{3.022}$) indicated that at 2.20 y old (age corresponding to the minimum landing

size of *T. trunculus* – MLS = 50 mm SL) specimens achieved 10.86 g in total weight. The estimated maximum asymptotic total weight ($W_\infty = 49.97$ g) was lower than the maximum total weight registered in samples from the Ria Formosa lagoon (58.20 g), but yet again this was an exceptionally heavy individual, because amongst 2401 *T. trunculus* weighed during a 1-y sampling program, only one specimen was heavier than the asymptotic total weight estimated in the present study ($W_\infty = 49.97$ g).

Therefore, and although the von Bertalanffy growth model has been criticized for not adequately representing growth of the entire size range of organisms, in the present case both size (shell length) and weight (total weight) data fitted the growth model satisfactorily.

Aquaculture and Fisheries Considerations

Despite being slightly low and underestimated because of the dominance of adult specimens in the samples, the growth rate estimated through mark/recapture experiments for *T. trunculus* (1.0 mm/month) may still create some expectations in terms of the potential of this species for molluscan aquaculture, considering that laboratory hatched specimens grow at a much higher rate (2.5 mm/month during the first 4 mo of life) and that the von Bertalanffy growth function indicated an age of 2.20 y to attain the minimum landing size for this species (50 mm SL i.e., 10.86 g TW).

Because environmental and feeding requirements of *T. trunculus* are not demanding, the culture of this gastropod species could become profitable in the near future, when the crucial phases of the species reproductive cycle (spawning and posthatching development) are better known. Moreover, because of an increasing demand for gastropods in the seafood market, the commercial value of *T. trunculus* has been continuously rising (reaching values of €10–15/kg for first sale) and its abundance in the Ria Formosa lagoon apparently has been decreasing over the last years, prob-

ably caused by illegal fishing and consequent overexploitation of the resource.

ACKNOWLEDGMENTS

The authors thank Pedro Pousão-Ferreira for allowing these mark/recapture experiments in an earth pond of the Olhão Fish Culture Pilot Station, as well as their collaborators for monitoring

the seawater parameters; João Tata-Regala for his help in fencing the earth pond; Susana Carvalho, Rita Constantino and João Cúrdia for their assistance during the recapture operations and Dr. Scoresby Shepherd and Dr. Fred E. Wells, whose suggestions greatly improved the manuscript. This study was partially funded by a PhD grant from the Fundação para a Ciência e Tecnologia (FCT: SFRH/BD/5139/2001) and by the DIVERAQUA Project (Interreg IIIA).

ECONOMIC IMPACT ASSOCIATED WITH THE RECREATIONAL SCALLOP SEASON IN CITRUS COUNTY, FLORIDA, USA.

Chuck Adams¹ and Don Sweat.² ¹Florida Sea Grant and Food & Resource Economics Department, University of Florida, PO Box 110240, Gainesville, FL 32611, USA. ²Florida Sea Grant, 830 First Street South, St. Petersburg, FL 33701, USA.

Because declining stock conditions, the commercial harvest of bay scallops (*Argopecten irradians*) in Florida was banned during 1994. During that same year, a recreational season was established on the Gulf coast of Florida in the area between Aripeka and Mexico Beach, Florida. In 1995, the recreational season was limited to a more restricted region—the area north and west of the Suwannee River. Because of a number of factors, including efforts to re-establish bay scallops through stock enhancement activities, the recreational season was re-opened during 2002 in the region between Aripeka and the Suwannee River. Within this region, the highest concentration of scallops, and thus recreational scalloping activities, is near the mouths of the Homosassa River and the Crystal River, in Citrus County. The recreational scallop season runs from July 1 to September 10 of each year. During this period, local businesses experience increase business volumes because recreational scallopers arrive in large numbers attempting to harvest daily bag limits. Anecdotal evidence and reports suggest that the recreational scallop season provides a significant boost to the local economy, because recreational scallopers purchase fuel, food, supplies and lodging accommodations during their stay. In addition, many of these recreational scallopers come from outside the area, thereby bringing in new dollars to the local economy. The purpose of this study is to estimate the economic impact associated with the 2003 recreational scallop season in Citrus County, Florida. This information would help resource managers and county business representatives better understand the economic and social implications of ensuring a sustainable recreational harvest of bay scallops. Several personal interviews were conducted immediately after the 2003 season. A total of 99 interviews were conducted. The interviews were conducted with representatives of a variety of business types in the area. The business types included fishing guides and dive shops, restaurants, lodging accommodations, convenience stores and gas stations and retail shops. Sales information associated with clientele involved in recreational scalloping was solicited. Estimates of changes in business sales during the scallop season were requested. Information on the resident versus non-resident sales was sought. The sample survey findings were then extrapolated to the total business population in the region. As a result, the increase in business sales activity during the 2003 recreational scallop season was estimated to be \$1.4 million. Of this amount, approximately \$900,000 was associated with non-resident expenditures. An estimate of economic impact associated with the 2003 scallop season was then developed. The changes in business activity were entered into a regional economic modeling package, IMPLAN Pro. This model provides estimates of the economic impacts associated with changes in business activity within a region. This impact includes the “multiplier” effects that recre-

ational scalloping-related expenditures have on the local economy. As a result, the total economic activity associated with non-resident expenditures on recreational scalloping activities during 2003 in Citrus County, Florida was \$1.6 million. Local incomes increased by \$636,000, and local business taxes increased by \$110,000 because of these non-resident expenditures. Approximately 35 new jobs are associated with the recreational scallop season. Thus, the recreational scallop season provides economic impact to the regional economy. Further research is needed to better refine the economic impact estimates by business type and to expand the analysis into other regions of the state where the recreational scallop season occurs.

SWIMMING BEHAVIOR OF *PECTEN MAXIMUS* LARVAE. Sissel Andersen, Anne Berit Skiftesvik and Howard Browman, Institute of Marine Research, Austevoll, N-5392 Storebo, Norway.

Institute of Marine Research (IMR) is working to support the development of a sustainable aquaculture in Norway and great scallop (*Pecten maximus*) is one of the marine species on focus. IMR has worked for several years to improve the results for the production of great scallop spat. As part of a project to investigate several factors on larval performance, larval swimming behavior was observed using Silhouette (shadow) video photography. The factors larval stocking density, algal concentration, and light intensity were investigated at different larval ages. Factors affecting swimming behavior are likely to be important for the energy budget. Batches of scallop larvae were transferred from the bivalve hatchery Scalpro AS 3 days after spawning, and placed in 100–300-L stock tanks with flow-through of seawater and algae. Rearing methods were those employed for flow-through systems at IMR-Austevoll: temperature of 16°C to 17°C, flow rate of 1 tank volume per day, continuous room light, continuous addition of a mixture of three algal species (*Isochrysis galbana*, Tahitian), *Pavlova lutheri* and *Chaetoceros mulleri* mixed in the ratio 1:1:1, algal concentration in rearing tanks at 10 cells/μL and an initial stocking density of 5–8 larvae/mL. Larvae were starved 12 to 24 hours prior to experimental treatment and observations. Silhouette (shadow) video photography (SVP) was used to record the behavioral responses of scallop larvae. Image quality is unaffected by ambient light-level silhouettes are cast equally well under full sun or in complete darkness. It allows filming of events in a large depth of field (~15 cm), with a relatively large field of view (here ~15 cm). The illumination system consisted of 2 components: a light intensity-controlled 1000-W Xenon arc lamp connected to an ultraviolet (UV, 280–400 nm)-visible liquid light guide and a 200-W Xenon arc lamp. Larval swimming behavior was affected by all three factors investigated. Also, the ratio of larvae exhibiting the clock-wise helical swimming pattern at an early stage reflected the quality of the larval batch in terms of survival. The effect on swimming behavior increased as a function of exposure time from 3 minutes up to 4 hours.

FLOW-THROUGH LARVAL SYSTEMS WITH DIFFERENT ALGAL CONCENTRATIONS. Sissel Andersen,¹ Gyda Christophersen² and Thorolf Magnesen.² ¹Institute of Marine Research, Austevoll, N-5392 Storebo, Norway; ²Centre for Studies of Environment and Resources, University of Bergen, PO Box 7800, 5020 Bergen, Norway

Institute of Marine Research (IMR) is working to support the development of a sustainable aquaculture in Norway. Great scallop (*Pecten maximus*) is one of the marine species being focused on in developing the aquaculture industry. IMR has worked together with the bivalve hatchery Scalpro AS and the University of Bergen for several years to improve the results for the production of great scallop spat. As part of a project to investigate several factors on larval performance in production scale units, larvae were grown with different algal concentration in the rearing tanks. Larval groups were transferred 3 days after spawning from Scalpro AS to large-scale facilities at Austevoll, IMR. The larvae were kept in 2,800 litres up-welling cylindrical tanks with conical bottom. Standard rearing method was used: a flow rate of one tank volume per day, temperature 15°C to 17°C and a diet consisting of *Isochrysis galbana* (Tahitian), *Paylova lutheri* and *Chaetoceros mulleri* mixed in the ratio 1:1:1. The initial larval stocking density was 3–5 larvae/mL. The variation between tanks was first tested keeping the algal concentration in the larval rearing tanks at 7 (± 3) algal cells/ μ L, and then larvae were reared keeping the algal concentration between 3 and 20 cells/ μ L. Also, one larval group was starved and not supplied with algae. Larval growth and survival was registered, as was the yield of competent larvae retaining on a 150 μ m mesh screen. The variation between tanks was low. There was no significant difference between tanks in mean shell height 21 days after spawning or larval yield on 150 μ m mesh 24 days after spawning. Mean shell height ranged between 162 \pm 26 and 170 \pm 25 μ m for larvae in the different tanks. Larval yield ranged between 27.4 and 34.8%. Algal concentration in the larval rearing tanks affected both growth rate and metamorphosis rate. Growth of starved larvae ceased 6 days after spawning. There were no significant differences in shell height between fed groups up to 13 days after spawning when the mean shell height was 134 \pm 10 μ m. Later there was a positive correlation between algal concentration and shell growth rate. However, there was no significant difference in shell growth between the two highest algal concentrations (16 and 20 cells/ μ L), and between the two lowest algal concentrations (3 and 8 cells/ μ L). Mean daily shell growth at 3 cells/ μ L was 23% lower than at 20 cells/ μ L. Generally survival 20 days after spawning was not significantly different between fed groups and varied between 85 and 96%. Survival in the starved groups was similar to fed groups 15 days after spawning but decreased rapidly to 9% 20 days after spawning. Larvae were harvested on a 150- μ m mesh screen and transferred to a production settlement system in the hatchery. Generally the yield of pediveligers on 150- μ m mesh screen increased with increasing algal concentration. Time to first harvest was shortest for larval groups

with the two highest algal concentrations: 22 days after spawning. The groups with the two lowest algal concentrations were harvested 27 days after spawning. Yield of pediveligers at first harvest varied from 24% to 48%, the highest value representing the highest algal concentration.

THE SOUTH AFRICAN SCALLOP *PECTEN SULCICOSTATUS*—PRELIMINARY RESULTS FROM INVESTIGATIONS OF REPRODUCTIVE CYCLE. Dale C. Z. Arendse,¹ Sissel Andersen,² Norman J. Blake³ and Grant C. Pitcher.¹ ¹Department Environmental Affairs and Tourism, Marine and Coastal Management, Private Bag X2, Rogge Bay, 8012, Cape Town, South Africa; ²Institute of Marine Research-Austevoll, N-5392 Storebo, Norway; ³College of Marine Science, University of South Florida, 140 7th Ave. South, St. Petersburg, FL 33701, USA

The local scallop *Pecten sulcicostatus* is presently being investigated as a potential species for mariculture in South Africa. As there is no commercial fishery for scallops in South Africa little is known about the ecology of the local species. Therefore this study was conducted to determine the reproductive cycle of *P. sulcicostatus*. Scallops were collected on a monthly basis in False Bay to calculate the gonadal somatic index (GSI) and to conduct histological studies on the gonads. The study began in August 2004 as a part of a Norwegian-South African cooperation funded by NORAD. Two size classes were collected, 40 mm to 59 mm and 60 mm to 110 mm. A steady decrease in the GSI took place for both size classes from August (winter) to November (spring) 2004. The GSI in August 2004 for the larger and smaller size classes was 12.8% and 11.4% respectively. In December (summer) 2004 the gonads of the larger size class were completely spent with no discernable difference between the male and female sections of the gonads. The mean GSI for this period was only 5.2%. The GSI in both size classes started to increase again in January 2005. The trend in gonad development indicates that *P. sulcicostatus* might reach its spawning peak in winter. The mean concentrations of chlorophyll *a* in winter are lower during spring, summer and autumn. Wind also shows a strong seasonality over False Bay, with strong south-easterly winds dominating in summer, resulting in localized upwelling. Because of a significant stratification, the bottom temperature is 1°C to 3°C lower in summer than in winter.

RISE AND FALL OF THE CALICO SCALLOP (*ARGOPECTEN GIBBUS*) FISHERY OF FLORIDA, USA. Bill Arnold. Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission, 100 Eighth Avenue SE, St. Petersburg, Florida 33701, USA.

The calico scallop (*Argopecten gibbus*) supports an important commercial fishery on the east coast of Florida, USA. Peak landings were realized from the east Florida shelf during the 1980s,

with substantially fewer landings before and after that time. That pattern of landings could indicate that scallops were unusually abundant during the 1980s and that pre- and post-1980s landings data reflect more typical standing stock values. However, results from exploratory fishing cruises conducted by federal fishery research vessels beginning in the late 1940s and continuing through the 1960s suggest that large stocks of calico scallops were extant off North Carolina, east Florida, and in the Gulf of Mexico. Those stocks were not exploited until the 1980s because the processing machinery necessary to efficiently handle the landed product was not previously available. Once an efficient processing method was developed and implemented, the fishery rapidly expanded and calico scallop populations on the east Florida shelf were intensively exploited. Subsequent to the 1980s, harvest and processing capabilities remained in place, but commercial landings fell to near zero. It is therefore possible to define three phases in the history of the calico scallop fishery in Florida. During phase 1 (approximately 1950–1980), exploratory fishing activities indicated that large numbers of scallops were known to exist on the east Florida shelf and in other areas of Florida. Those exploratory fishing efforts extended over many years, indicating that the abundance of calico scallops was not an ephemeral situation but was instead a relatively constant feature of the east Florida shelf. During phase 2 (approximately 1980–1990), the needed processing equipment was deployed and the commercial fishery expanded rapidly. To estimate harvest during this phase of the scallop fishery, consider that a large calico scallop adductor muscle weighs approximately 4 g, equivalent to about 110 scallops harvested per pound of meat landed. Thus, during 1984 alone, more than 4.4 billion scallops were harvested. During phase 3 (approximately 1990 to present), the scallop population on the east Florida shelf declined and the commercial industry went with it. Small numbers of scallops were harvested from that area during the early 1990s, but the commercial fishery at the beginning of the 21st century is essentially non-existent. Possible causes of the purported collapse include one or a combination of the following factors: overfishing, habitat loss, disease, or natural variation. Fishing activities target high-density patches of scallops, so it is possible that removal of large numbers of scallops during the 1980s eliminated many high-density patches and reduced the reproductive viability of the population, ultimately leading to population collapse. Harvesting activities also remove large amounts of calico scallop and other shell. That shell provides a primary settlement substrate for calico scallops in what is an otherwise featureless sand bottom. Thus, fishing activity has resulted in the destruction of the very habitat upon which recruiting scallops depend. A protistan parasite of the genus *Marteillia* was first recorded from the east Florida calico scallop beds in 1991. Although there is no direct evidence that this parasite caused mortality in the scallop population, species of *Marteillia* have been implicated in other bivalve mass mortality events. Finally, the east Florida shelf is characterized by a dynamic oceanographic regime that is strongly influenced by Gulf Stream meanders

and resultant seasonal upwelling. Changes in that regime, especially relatively long-term changes associated with ENSO or NAO events, could have altered the population dynamics of calico scallops on the east Florida shelf. Economic factors may prevent the return of the calico scallop fishery in Florida even if the scallop population rebounds. First, a bay scallop (*Argopecten irradians*) aquaculture industry has been developed in China, and that industry produces scallop meats that can be shipped to the United States and sold more cheaply than calico scallops can be harvested from the wild fishery and sold in the United States. Thus, there is little economic incentive to invest in the calico scallop industry even if the animal once again became abundant. Second, Port Canaveral, Florida is the primary landing port for calico scallops on the east coast of Florida but also has become a major cruise ship terminal. Cruise ship activities and calico scallop processing activities are somewhat incompatible because of the odor and noise that emanate from the processing facilities. Additionally, shoreside sites that once supported processing facilities are now being converted to more lucrative marinas and terminals, with the result that there is simply no room for the calico scallop industry at Port Canaveral.

A BRIEF HISTORY OF BAY SCALLOP (*ARGOPECTEN IRRADIANS*) RESTORATION EFFORTS IN FLORIDA USA WATERS. Bill Arnold¹ and Norman J. Blake². ¹Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission, 100 Eighth Avenue SE, St. Petersburg, Florida 33701, USA; ²College of Marine Science, University of South Florida, 140 Seventh Avenue S, St. Petersburg, Florida 33701, USA.

Bay scallops (*Argopecten irradians*) once supported important commercial and recreational fisheries in Florida waters, and archaeological evidence suggests that they contributed to the cultural fabric of native Floridians many centuries prior to European invasion. However, in recent decades many of the local populations that comprise the Florida metapopulation of bay scallops have collapsed with the result that the entire metapopulation may be imperiled. In an effort to stabilize the bay scallop metapopulation in Florida, the State of Florida first instituted severe harvest restrictions and then instituted a restoration program. The goals of this combined passive-active approach to rebuilding scallop populations were to (1) prevent further loss of reproductively viable populations and (2) rebuild populations in areas where habitat appeared to be amenable to supporting viable scallop populations. Historic and anecdotal information indicates that bay-scallop populations in Florida waters once extended from at least West Palm Beach on the east coast to Pensacola in the Florida panhandle. By the early 1980s, all populations from Anclote south had essentially collapsed. At that time, the State instituted regulations to create both a harvest season and a five-gallon (19 L) bag limit. By the early 1990s, additional populations between Anclote and

Crystal River also appeared to have collapsed. In response, the State implemented additional harvest restrictions and initiated a population restoration program that continues to this day. The success of those management and restoration efforts is equivocal and is the topic of this presentation. Modifications to the bay scallop management regime were initiated in 1994 with the complete closure of the commercial fishery, closure of the recreational fishery south of the Suwannee River, reduction of the fishing season from 9 months to 3 months, and a reduction in the bag limit to two gallons (7.6 L) per person per day. The next year, the season was further reduced to approximately 2 months per year. However, despite these drastic restrictions on harvest, no substantial increase in scallop abundance was observed between the years 1994 and 1998. Efforts to restore local scallop populations were instituted in 1998 as a joint effort between the Florida Fish and Wildlife Conservation Commission and the University of South Florida College of Marine Science. This effort involved planting juvenile scallops at high density in protective cages at various sites along the SW coast of Florida. Those juveniles would then grow to adulthood within the cage, thus ensuring high density and relatively high fertilization efficiency during subsequent spawns. The resultant offspring would then settle to the local seagrass beds and thereby repopulate the area. Population monitoring within the target area indicated that scallop density did increase according to prediction in at least a subset of the target area. Scallops were first planted in spring 1998, subsequently achieved adulthood, and spawned during fall 1998. Thus, it would be expected that offspring from those planted scallops would achieve adulthood in spring 1999 and would be detected during sampling surveys conducted in the summer of 1999. That expectation was realized as an order-of-magnitude increase in scallop abundance at the Homosassa study site between June 1998 and June 1999. Additional planting efforts were conducted in 1999 and 2000, with the result that scallops increased by yet another order of magnitude between June 1999 and June 2000 and remained similarly abundant in 2001. However, funding for the restoration effort ended in 2000 so no scallops were planted in spring 2001. Scallop abundance immediately decreased in the Homosassa target area, and by June 2004 scallop abundance had fallen to background levels despite a continuing but smaller-scale restoration effort. Initial interpretation of the results of management and restoration activities, including data acquired through summer 2001, suggested that efforts to rebuild scallop populations in Florida waters had been successful although it was not clear if management, restoration or a combination of the two was responsible for the resurgence. Inclusion of more recent data, as described earlier, suggests that restoration activities may have been the pre-eminent factor, because scallop abundance at the Homosassa restoration site rose and fell in concert with restoration activities. Whether governmental organizations are willing to devote the necessary resources to a continuing scallop restoration program remains to be seen.

SEASONAL VARIATIONS IN CHEMICAL, PHYSICAL, TEXTURAL AND MICROSTRUCTURAL CHARACTERISTICS OF ADDUCTOR MUSCLES OF GIANT LION'S PAW SCALLOP (*NODIPECTEN SUBNODOSUS*). Ana I. Beltrán-Lugo,¹ Alfonso N. Maeda-Martínez¹ and Ramón Pacheco-Aguilar.² ¹Centro de Investigaciones Biológicas del Noroeste (CIBNOR), Mar Bermejo No.195, Col. Playa Palo de Santa Rita, La Paz, Baja California Sur 23090, México; ²Centro de Investigación en Alimentación y Desarrollo (CIAD), Carretera a la Victoria Km. 0.6 Hermosillo, Sonora 83000, México

The giant lion's paw scallop (*Nodipecten subnodosus*) is one of the most commercially important species of scallops in Mexico. The quality of its adductor muscle, the main edible portion, depends greatly on texture and color characteristics. The texture of fish muscle is determined by many factors, including chemical composition (Crapo et al. 1999) and muscle structure (Bjørnevik et al. 2004). These characteristics vary seasonally in response to reproductive activity and availability of food. For lion's paw scallop, how the quality parameter is influenced by seasonal variations in the composition of the adductor muscle have not been investigated. This study analyzed the effects of season on chemical, physical, textural and microstructural characteristics of adductor muscles of giant lion's paw scallop (Fig. 1). Samples of scallops (average size 66.3 ± 6.9 mm) were harvested in winter (January), spring (April), summer (September) and fall (November) 2003 from an aquaculture farm on the Pacific coast of the Baja California Peninsula, México. Morphometric variables were recorded for a sample of 30 specimens to calculate muscle index and gonadosomatic index. These indices were used as indicators of physiological condition of the organisms at the time of harvest. To assess the quality of the adductor muscles; proximate composition (moisture, protein, lipids, ash, and carbohydrates); postmortem pH; color parameters (L^* , a^* and b^*); water-holding capacity; texture (Warner-Bratzler shear test) and microstructure were analyzed (Fig. 2). We observed that organisms sampled in summer showed higher muscle and gonadosomatic indices. Chemical composition varied throughout the year. Levels of moisture and lipids were significantly lower in the summer samples but carbohydrate content was higher. Post-mortem pH in summer was lower than other seasons. Lower water-holding capacity in the summer samples seems to be influenced by the lower pH in adductor muscles. Slight but significant changes in color characteristics of adductor muscles were observed in all seasons. Color is known to be related to lipids content; however, we found no support for seasonal color differences to be related to this chemical component. Warner-Bratzler shear test values yielded the poorest muscle texture in summer; most likely related to lower pH, water-holding capacity, and wider spacing between muscular fibers and structural alterations at this season. Our results indicate that the quality of adductor muscle is somewhat poorer if collected in summer even though scallops yield the highest muscle weight of all seasons. In contrast, the quality of muscles in winter is the highest, but the muscle yield is 11.5% lower than the summer.

With these results and the parameters of quality that the markets demand, the scallop farmer will be able to refine its harvest program.

CLOSED AREAS AND STOCK ENHANCEMENT OF SCALLOPS—WHAT'S THE CATCH? Bryce D. Beukers-Stewart, Belinda J. Vause, Matthew W. J. Mosley and Andrew R. Brand. Port Erin Marine Laboratory, University of Liverpool, Port Erin, Isle of Man IM9 6JA, British Isles.

The use of closed areas and stock enhancement to manage fisheries is becoming increasingly popular around the world. Scallop fisheries appear to be particularly suited to this type of management, which has produced highly productive and stable fisheries in countries such as Japan, China, New Zealand and the United States. A small area (2 km²) off the SW coast off the Isle of Man, British Isles, has been closed to fishing by towed gear (i.e., dredges and trawls) since 1989. During closure the density and biomass of great scallops (*Pecten maximus*) in the closed area has increased at an accelerating rate such that by 2004 the density, exploitable biomass and reproductive biomass of scallops was 5.5, 8.0 and 9.5 times greater, respectively, than on the adjacent fishing ground. In addition, scallop recruitment and commercial catch rates have also increased during the study period on the several fishing grounds surrounding the closed area. These patterns may be the result of very high levels of scallop reproduction in the closed area and subsequent larval export, and/or they could be explained by spillover (movement) of scallops from the closed to the fished areas. However, fluctuations in scallop populations can also be driven by various other factors such variation in hydrographic conditions or predator abundance. Identifying and quantifying the mechanisms by which closed areas may benefit fisheries is crucial if they are to be adopted as a widespread management tool. This study describes a new project examining the effectiveness of combining closed area management with stock enhancement. The initial phase of this project involved importing juvenile scallops from the Isle of Skye, Scotland for direct seeding on the seabed. A small area of seabed (~1 km²), adjacent to the original closed area, was closed to mobile fishing gear for 3 years from June 2003 to protect these scallops while they grew to commercial size. It was envisaged that this reseeded exercise would “kick start” the recovery of the newly closed area. Protecting the scallops during their critical juvenile phase should also improve their survival and growth – enhancing yields when the area is re-opened to fishing. In addition, because the reseeded scallops were likely to be genetically different from

the local stock, it was intended to use this feature to track their dispersal and potentially quantify any larval export from the new closed area. In an attempt to reduce the number of predators (starfish and crabs) prior to re-seeding, the area to be closed was initially subject to 2 days of commercial scallop dredging at the end of May 2003. It was calculated that the entire seabed within this area was dredged at least twice during this procedure. Dive surveys were then done to obtain background estimates of the density of scallops and other benthic species. For the reseeded exercise, approximately 45,000 scallops that had been reared in suspended culture were collected from the Isle of Skye in mid June 2003 and transported to the Isle of Man using a vivier lorry. Scallops came from two different farms and were mainly 2- (42%) and 3- (53%) year-old individuals. Mean sizes were 55.4 mm SL for 2-year olds and 69.2 mm SL for 3-year olds. Scallops from one farm were very heavily encrusted with epifauna, mainly barnacles, and both sets of reseeded scallops were easily distinguished from local scallops by their size and appearance. On arrival at the Isle of Man the reseeded scallops were transported by boat to a designated 50 m × 100 m plot within the new closed area and released. Survival after 2 weeks was assessed in the laboratory and the field via diver surveys. The encrusted scallops suffered substantial mortality in the laboratory (>80%), whereas the clean batch showed greater than 95% survival. In the field the respective figures were 33% survival for the encrusted scallops and 60% for clean scallops (total mean survival 42.3%). These diver surveys also revealed a dramatic aggregation of predators (mainly the common starfish *Asterias rubens* and edible crab *Cancer pagurus*) in the reseeded plot, whose densities had increased 20-fold since the background survey. Thirty percent of dead 2-year-old scallop shells displayed obvious crab damage, compared to only 12% of dead 3-year-old scallop shells. Dive surveys were repeated in September 2003 and July 2004 (3 and 12 months after reseeded respectively), both within the reseeded plot and at various distances outside up to 500 metres away. After 3 months the density of live reseeded scallops in the plot had dropped dramatically to less than one percent of the original reseeded density. However, there was no corresponding increase in the density of dead scallops; in fact this had dropped by 75%. In comparison, the density of scallops outside the plot had increased from 0.75 m⁻² prior to reseeded to 5.0 m⁻² in September 2003, and remained high in July 2004 (3.9 m⁻²). These patterns seem to have been strongly driven by dispersal of scallops from the reseeded plot, because there was very little natural recruitment during this period. Reseeded scallops were found up to 500 m from the reseeded plot and accounted for at least 28% of all scallops in the new closed area in July 2004. Based on these estimates it was calculated that at least 10,920 reseeded scallops were alive in July 2004. These scallops all appeared to belong to the clean batch, giving a survival rate of 52% for these scallops but no survival of the encrusted type. Preliminary work has also demonstrated that it is possible to distinguish between the Skye and Manx scallops

using microsatellite analysis. Samples collected during the dive surveys and from spat collectors in 2004 are currently being analyzed to refine our estimates of scallop dispersal and investigate the possibility of larval export from breeding among the reseeded scallops. Future reseeding exercises would benefit from ensuring that the scallops to be reseeded are in good health and that the area to be reseeded is more effectively cleared of predators. However, the reseeding exercise does appear to have kick-started the recovery of scallop populations in the new closed area. This should lead to increased breeding within this area and potentially larval export to the surrounding fishing grounds. The genetic distinctness of the Skye scallops may allow larval export to be quantified. An experimental fish-down of the new closed area is planned for mid 2006 to assess the fisheries benefits of enhancing and closing an area for 3 years. Given our results to date, a combination of closed area management and stock enhancement seems to hold considerable promise for improving the inshore scallop fishery around the Isle of Man.

GENOTYPIC EFFECTS OF GLYCOLYTIC ENZYMES ON THE LEVELS OF ENERGY SUBSTRATES IN GONAD AND MUSCLE OF *ARGOPECTEN PURPURATUS*. Katharina Bröckordt and Federico Winkler. Center for Advanced Studies in Arid Zones (CEAZA) and Marine Sciences Faculty, Universidad Católica del Norte, Coquimbo, Chile.

The polygenic nature of most quantitative traits makes difficult to understand the biochemical genetic basis of phenotypic variation. One way to examine the interactions between the forces that outline the phenotype of an organism with those that maintain its underlying genetic variation, is to inspect the variation at a specific gene, especially one whose biochemical function is known, and

then recognize its effect on the phenotype (Krause & Bricelj 1995). Glycolytic and pre-glycolytic enzymes have an important function in the storage and utilization of energy substrates in the gonad and the muscle. We examined the genotypic effect of 5 glycolytic and pre-glycolytic polymorphic allozymes (ODH, APK, GPI, G3PDH and PGD) on the variation in energy substrate contents (carbohydrates, lipids and proteins) present in gonad and adductor muscle of adult *Argopecten purpuratus*. The effect of adult allozymes genotype was assessed in 180 scallop muscles by horizontal starch gel electrophoresis. In the same individuals the content of carbohydrates, proteins and lipids in the muscle and gonad were determined using the methods described by Dubois et al. (1956), Lowry (1951) and Mann and Gallager (1985), respectively. *A. purpuratus* muscle showed a significant variation on carbohydrate content, related to the genotype of *ODH**, *APK** and *G3PDH** (Fig. 1). The presence of the common alleles *ODH*¹¹⁰ (homozygote), *APK*¹⁴² and *G3PDH*⁸⁵ was related to the highest levels of muscle carbohydrates. Muscle protein content was highest when the alleles *G3PDH*⁸⁵, *PGD*¹⁰⁸ and *PGD*⁸⁰ were present. Lipid content in the muscle was not affected by any allozyme genotype we tested. In the gonad, the occurrence of the alleles *ODH*¹¹⁰ and *APK*¹⁴² was related to the highest levels of carbohydrates and lipids. In addition, gonad carbohydrate content was greater when the allele *GPI*¹⁰⁸ was present (Fig. 2). Finally, the occurrence of the alleles *APK*¹⁴², *G3PDH*⁸⁵, *GPI*¹⁰⁸ and *PGD*⁸⁰ implied a higher level of proteins in the gonad. Our results show a clear association between the *ODH**, *APK**, *GPI**, *G3PDH** and *PGD** genotypes and the levels of the three energetic substrates in the adductor muscle and gonad of *A. purpuratus*. Considering the great importance of these tissues in reproduction and escape response, the occurrence of alleles associated with highest contents of carbohydrates, lipids or proteins may have an adaptive importance to *A. purpuratus*. The effect of specific alleles on productive

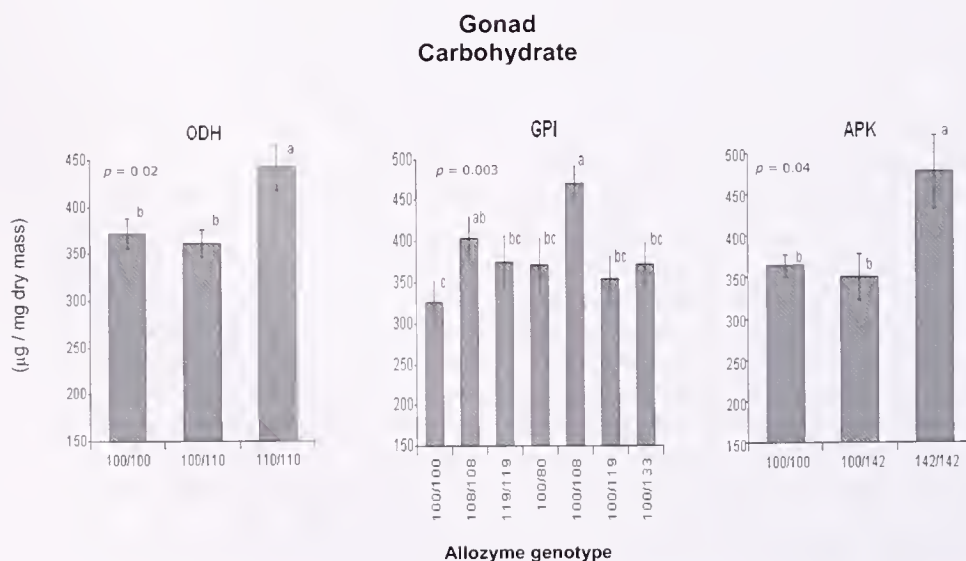

Figure 1. *Argopecten purpuratus*. Effect of genotype at *ODH**, *G3PDH** and *APK** loci on muscle carbohydrate content.

Figure 2. *Argopecten purpuratus*. Effect of genotype at *ODH**, *GPI** and *APK** loci on gonad carbohydrate content.

traits also should be considered for genetic management strategies in scallop aquaculture.

EMBRIOLOGICAL DEVELOPMENT OF CATARINA SCALLOP *ARGOPECTEN VENTRICOSUS*. Carlos Cáceres-Martínez,¹ Jorge Chávez-Villalba,² Jorge I. Cáceres-Puig¹ and Jorge A. Massó-Silva.¹ ¹Universidad Autónoma de Baja California Sur, Km 5.5 Carretera al Sur, La Paz, BCS, 3080, México; ²Centro de Investigaciones Biológicas del Noroeste, Unidad Guaymas, AP 349, Guaymas, Sonora 85465, México.

During the last 25 years different efforts have been made for the knowledge of biological history of *Argopecten ventricosus* in the North West of Mexico, in spite of the capability of hatchery seed production and the knowledge of larvae development, the embryology of this species remains undescribed. The objective of this work is to describe the morphological changes during fecundation, segmentation and gastrulation of *A. ventricosus*.

Twenty-five scallops were collected in La Paz Bay and transported to the laboratory. After they were cleaned, they were stimulated by thermal shock for spawning. When spawning was initiated, the scallops were set in individual containers to obtain separated gametes, male and female gametes were combined and the embryological development was followed until the appearance of the trocophore larvae. The incubation condition took place in filtered (1 µm) and UV irradiated seawater maintained at 21 °C in three 10-L plastic containers. After fertilization, samples were taken for microscopic, micro-photographic and micro-video ob-

servations. All the changes were recorded for description of embryonic development. The eggs of *A. ventricosus* were spherical with diameter of 45 µm average, which means, quite small in comparison to *Pecten maximus* eggs (79 µm) (Paulet et al. 1988). After 29 minutes from fertilization, we observed the first polar body on 15% of the eggs, in vegetal pole 15 minutes later we observed the first division where the first segmentation plan (meridional) was easily recognized. The segmentations in scallops were described for *Chlamys opercularis*, *Placopecten magallanicus*, *Argopecten irradians*, *Patinopecten yessoensis*, *Chlamys hastate* and *Pecten maximus* as was noticed by Casse (1995). During the first division, we observed the formation of the polar lobule and its fusion with the blastomere. One hour and 25 minutes after fertilization, the second segmentation edge appeared, the second division was present in the 10% of embryos, 1 hour 45 minutes after fertilization and 5 minutes later, 80% of embryos showed the third division (equatorial). After the fourth division, we could not differentiate the segmentation plans until they reached the stereoblastule stage, ending the segmentation process and beginning the gastrulation with morphogenic movements as epibolia and invagination for the formation of blastopore in the vegetative pole. As it was reported for molluscs, the gastrula stage was ciliated (Cragg, 1980), and its movement maintained the embryo rotating over by itself all the time. The experiment finished 6 hours 12 minutes after the fertilization started, when the trocophore larvae were functional.

ROUND SCALLOPS AND SQUARE MESHES—PROMISING FIELD TRIALS WITH BYCATCH REDUCTION DEVICES (BRDS) REDUCE BOTH BYCATCH AND UNDERSIZED SCALLOP CATCHES. Matthew Campbell,² Keith Chilcott,² Anthony Courtney,² Shane Gaddes,² Peter Kyne,¹ Darren Roy,² Mark Tonks² and Michael O'Neill.²

¹School of Biomedical Sciences, Department of Anatomy and Developmental Biology, University of Queensland, St Lucia 4072, Queensland, Australia; ²Queensland Department of Primary Industries and Fisheries, Southern Fisheries Centre, PO Box 76 Deception Bay 4506, Queensland, Australia.

Benthic trawl fisheries, such as those for prawns and scallops on the Queensland east coast, generally produce large amounts of bycatch, which is comprised of hundreds of species of small fish and invertebrates. The amount of bycatch produced greatly exceeds that of the target catch. A research project funded by the Australian Fisheries Research and Development Corporation (FRDC) quantified the catch rates and composition of bycatch in the fishery and tested a range of bycatch reduction devices (BRDs). A 9-day research charter conducted in the scallop fishery demonstrated that bycatch could be reduced by 78% by using nets with a turtle excluder device (TED) and a square mesh codend BRD installed, compared to a standard net. If scallop fishers used the devices, it would reduce bycatch by several thousand tons annually. Whereas the research was undertaken to address bycatch, it also found that the devices reduced catch rates of undersized scallops by 63%. Square mesh codends, in particular, show great potential for regulating the minimum size of scallops and lowering incidental fishing mortality, as well as significantly reducing bycatch.

A STEREOLOGICAL STUDY OF THE REPRODUCTIVE CYCLE OF *PECTEN MAXIMUS* IN MÁLAGA. EFFECTS ON ITS AQUACULTURE. Jesús Campos,¹ Juana Cano,² Carmen Vázquez¹ and Francisco J. López.² ¹Centro Oceanográfico de A Coruña, Instituto Español de Oceanografía, PO Box 130, 15080 A Coruña, Spain; ²Centro Oceanográfico de Málaga, Instituto Español de Oceanografía, PO Box 285, 29640 Fuengirola (Málaga), Spain.

The great scallop, *Pecten maximus* L., is a bivalve belonging to the family Pectinidae. This species is distributed all along the east coast of the Atlantic Ocean, from Norway to Mauritania, and enters the Alboran Sea. Numerous studies have been carried out on the reproductive cycle of this species at different locations on the European coast, pointing to the varying behavior of the great scallop depending on the zone and year when there are different environmental conditions. (Paulet et al. 1988, Paulet & Boucher 1991, Strand & Nylund 1991, Pazos et al. 1996). To develop culture systems of a particular species, it is necessary to have an understanding of its reproductive biology. In 1997 studies began with a view to develop the culture of the great scallop in Málaga, which has the largest extension of natural banks on the Iberian

peninsula. Up until the year 2001 the reproductive cycle had only been studied in wild specimens of this species collected from the naturally occurring populations near the area where the culture is carried out (Román et al. 2001). Cano and Campos (2003) studied the reproductive cycle, age at onset of maturity and spawning season of cultured scallops on the basis of gonad condition indices, and they compared these data with the reproductive cycle of wild scallops, finding the sexual behavior of both scallops to be similar. This work discusses the knowledge of the reproductive biology of *P. maximus* on the basis of the evolution of the gonad condition indices as well as using stereological studies and oocyte size frequency, which are the most objective methods available to evaluate sexual maturity. The culture was carried out in a park located opposite the fishing port of Fuengirola (Málaga), which has mean depths of 20 m. Spat was obtained from collectors moored from April to July, 2001 and removed in September and October. Spat detached in September and October were moored on a longline at 10-m depth below the bottom in round culture trays 40 cm in diameter at a stocking density of 40 scallops/tray. In January, 2002 the animals were thinned out to a stocking density of 24 scallops/tray and in June, to 16 scallops/tray. Starting in January, 2002, 30 scallops were sampled monthly in 2002 and at intervals of every 2 weeks in the 2003. Scallop shell length and height (mm) were measured and the whole animal was weighed (g). The scallops were then dissected separating the muscle, gonad, digestive gland and remaining tissues (gills + mantle + foot), and wet weight as well as shell dry weight (g) were obtained. These values were used to calculate the condition indices of the different organs: $CI_{organ} = 100 * (\text{Shell weight} / \text{Organ dry weight})$. The gonads of 10 specimens were processed using traditional histological methods. Ten images of each gonad were randomly selected for analysis using stereological methods (Paulet 1990, Mestre 1992, Pazos et al. 1996). The mean diameter and area of each oocyte were recorded by counting and automatic measuring, and objects were selected by color range and size. Each gonad yielded data for more than 300 oocytes. The gonad occupancy index was also calculated ($GOI = \% \text{ occupied by oocytes that had not undergone atresia}$) for each image, taking into account the area occupied by the oocytes and the size of the standard visual field ($143,939 \mu m^2$). In 2002 the gonad condition index of the cultured scallops rose from January until May (1.07), followed by a drop until the month of September at which time recovery began with a second maximum being reached in January 2003 (2.22). In 2003 the index was seen to peak and drop consecutively from January to May (2.79). After this, it increased again in August (1.36) and dropped down to a minimum value of 0.5 in October. The summer rise was not observed in 2002, however we must bear in mind that the samplings were carried out monthly during that year. In fact, in a simultaneous experiment performed on wild scallops where sampling was done at intervals of every 2 weeks, values increased in mid-April and again at the beginning of June. These values would not have been recorded if sampling had been carried out monthly. The stereo-

logical analysis of the gonads shows that the volume of occupancy went from 0.5% in September 2002 to 95% in August 2003. Mean oocyte diameter ranged from 7.30 μm , corresponding to the few oocytes found in some of the gonads in September 2002, to 40.07 μm in August of the same year. The gonads were found to be lacking intrafollicular space, but had a considerable proportion of lysis. Oocyte atresia or lysis presented maximum values in late May, July and August, 2002 and in April, 2003, which was associated with an abundant proliferative activity and this might be seen as a response to the liberation of intrafollicular space, as happens during partial spawnings (C. A. Borzone et al. 2003). The greatest proportion of intrafollicular space would coincide with the spawnings recorded at the end of June and in September 2002 (total emptying of the gonad) and in early April, in July and late August in 2003. Because considerable lysis was found in August and to a lesser extent in May of 2002 and April 2003, it was assumed that these spawnings were not the best ones to be used in the procurement of spat. Cano and Campos (2003), reported that, in effect, the highest number of new attachments of this species took place in the collectors in April 2002 and in June, July and August of 2003. The size frequency distribution of the oocytes is in keeping with the gametogenic cycle described previously despite the fact that in most cases, the distributions showed that the follicles contain oocytes in varying stages of development. In 2002, we observed an increase in the frequencies of the larger sizes without the incorporation of new cohorts of young oocytes in May, which is characteristic of maturation, whereas in October, only oocytes measuring less than 35 μm were found to be present, indicating that one spawning had taken place. In 2003, there was an increase in the larger sizes in March, May and early August with the incorporation of young oocytes primarily in April, June and September. Based on all of these data the reproductive cycle of the great scallop in Málaga was concluded to be characterized by consecutive spawnings and recoveries from March until late summer, and the incidence of oocyte atresia depends on environmental conditions, basically temperature and the availability of food, with the spawnings producing greater or lesser spat settlement, accordingly.

REPRODUCTIVE CYCLE OF *MIMACHLAMYS VARIA* IN MÁLAGA AND EFFECTS ON ITS AQUACULTURE. Jesús Campos,¹ Juana Cano,² Carmen Vázquez¹ and Francisco J. López.² ¹Centro Oceanográfico de A Coruña, Instituto Español de Oceanografía, PO Box 130, 15080 A Coruña, Spain; ²Centro Oceanográfico de Málaga, Instituto Español de Oceanografía, PO Box 285, 29640 Fuengirola (Málaga), Spain.

The settlement of *Mimachlamys varia* in Málaga is very high and preliminary data on the tray culture of this species would suggest that it is a good candidate for aquaculture in this area (Campos & Cano 2003). The reproductive cycle of this scallop, which is essential in establishing the relationship between spawning and recruitment to develop the culture, has been studied under Project ACU00-008-C3-1 financed by the INIA. This research entailed a study of the gonad condition index as well as a histological study of the gonad, by means of stereological methods that shed light on gonad evolution and oocyte atresia. Spat removed from the collectors moored in 2001 were used. Over the course of 2 years, 2002 and 2003, 30 specimens were sampled monthly, and the scallops were separated by sex (males and females). Shell length and height (mm) were measured and the whole animal was weighed (g). The scallops were then dissected, separating the muscle, gonad, digestive gland and other tissues (gills + mantle + foot), and wet weight as well as shell dry weight were recorded (g). These were used to calculate the condition indices of the different organs: $CI_{organ} = 100 * (\text{shell weight} / \text{organ dry weight})$. In addition to the analysis of the female gonads, quantitative analyzes were performed using stereological methods (Paulet 1990, Mestre 1992, Pazos et al. 1996); 10 specimens were processed according to traditional histological methods. Ten images of each gonad were randomly selected for analysis. The mean diameter and area of

each oocyte were recorded by counting and automatic measuring, and objects were selected by color range and size. In general each gonad yielded data for more than 300 oocytes. The gonad occupancy index was also calculated ($GOI = \% \text{ occupied by oocytes that had not undergone atresia}$) for each image, taking into account the area occupied by the oocytes and the size of the standard visual field ($143,939 \mu\text{m}^2$). During the 2 years of the study, the male and female gonad condition indices present a similar cycle, maximum values occurring from February to May, after which they decline until they reach minimum values in August to September with recovery and maturation beginning again in winter. During the second year, values peaked in February followed by a sharp drop and quick recovery in March. With the onset of maturity, most of the gonads are male, but the relation between males and females changes over the course of the reproductive cycle so that the proportion of females is greater—as high as 70%—during the maturation stages, dropping to as low as 20% afterwards. The stereological analysis shows that from February to August partial spawning takes place and scallops recover from these events quickly. During these stages mature oocytes and pre-vitellogenic oocytes are visible on the follicle walls. In 2002, the greatest occupancy was seen in May and June (91.34%, 90.67%) and the gonads were practically empty in August and October (1.7% y 2% respectively). Maximum GOI occurred in February 2003 (95.90%) with recovery taking place from April to June. The mean diameter of the oocytes ranged from 18.35–35.18 μm . However, this is an underestimation because a gonad contains oocytes of varying sizes. The size frequency distribution of the oocytes indicates that a proliferative activity takes place practically throughout the whole year. The only time oocytes of $<10 \mu\text{m}$ do not appear is during the months of complete maturation in spring and early autumn, when the gonad is almost completely empty. Oocyte atresia or lysis was found in most samples, however it was highly abundant in the terminal stages of vitellogenesis in winter and summer. Therefore, we can see that although on February 5, 2003 occupancy amounted to 95.96% with the absence of lysis, on 21 February lysis was already 31%, and the high occupancy seen on 20 June (98%) was followed by a lysis of 44.5 % on 15 July. This may have been because of the fact that the conditions were not optimum for spawning and mature oocytes have a relatively short period of viability in the follicles. The spawning period is broad-ranging and lasts from February until late summer, but when there are high levels of oocyte atresia during the reproductive cycle, this leads to substantially low values on the gonad condition index, which are an impediment to the abundant settlement of spat in the collectors. This occurrence is supported by settlement data from the collectors moored to study the recruitment pattern of this species, where we observed that the highest settlements recorded over the 2-year study pertained to the collectors moored in April and removed in June and July. This corresponds to the release of gametes after the maximum maturation stages in April and May (Cano & Campos 2003). This is the time of year that the collectors should be moored

for the procurement of seed from the natural environment to be used in culture.

THE INFLUENCE OF DENSITY AND DEPTH ON THE GROWTH AND SURVIVAL OF *MIMACHLAMYS VARIA* AND *AEQUIPECTEN OPERCULARIS* IN MÁLAGA (SPAIN). Jnana Cano,¹ Jesús Campos² and Francisco J. López.¹ ¹Centro Oceanográfico de Málaga, Instituto Español de Oceanografía, PO Box 285, 29640 Fuengirola (Málaga), Spain; ²Centro Oceanográfico de A Coruña, Instituto Español de Oceanografía, PO Box 130, 15080 A Coruña, Spain.

For the development and optimization of a species in suspended culture it is well known that one of the most important aspects is to determine the depth and stocking density at which the species will thrive, resulting in the highest growth and lowest mortality rates. Málaga is an area of interest for the development of pectinid culture in Spain. The three commercial species (*Pecten maximus*, *Mimachlamys varia* and *Aequipecten opercularis*) have a high settlement rate, with an average of around 200 specimens per collector for the three species (Cano et al. 1999, Cano et al. 2003). Studies have been carried out to determine the optimum density-depth for the culture of *P. maximus* (Cano et al. 2000), but not for *M. varia* and *A. opercularis*. The study of these two species began in 2002 within the framework of Project ACU00-008-C3-1 financed by the INIA. Scallops were reared in Fuengirola (Málaga). Spat were procured from collectors moored between April and June and removed in October 2002. The suspended culture of the scallop (*M. Varia*) was started on October 24, 2002 and that of the queen scallop (*A. opercularis*) began on November 4, 2002. The aim of the experiment is to study the optimum density and depth to be used in culture. Trays containing *Mimachlamys varia* were moored on the longline at 5- and 15-m depths below the bottom. Two initial sizes were used—average sized specimens (height = 15.2 ± 2.16) and large specimens (height = $22.43 \pm$

1.39)—and three stocking densities: 60 and 100 scallops/tray for the average sizes and 40 scallops/tray for the large specimens. The trays containing *Aequipecten opercularis* were moored at 6- and 12-m depths below the bottom. An initial large size was used (height = 31.90 ± 3.51) and two stocking densities: 60 and 40 queens/tray. The scallops moored at 6 m and a density of 40 was lost due to a storm. In the two cases, the first sampling was carried out after 3 months (January and February, 2003), and the others in June, September and November 2003, which marked the end of the experiment. The samplings provided data on the size (height in mm), survival (number of live specimens in each sampling) and shell and flesh weight (gonad, muscle, digestive gland and remaining tissues) (g). *Mimachlamys varia*. The average-sized scallops moored at a density of 100 scallops/tray and at 5-m depth exhibited a mortality of 92% in the month of September, which forced us to terminate the experiment and remove all the culture trays. From the start of the culture, the scallops of this size moored at 5 m showed a higher growth rate for all the parameters sampled, than the ones moored at 15 m. The latter specimens, however, did not suffer any mortalities until the month of November, having a rate of 8%. In these trays moored at a depth of 15 m, growth was seen to slow down from September to November, and the scallops decreased in flesh weight and fractions. The average sized *Mimachlamys varia* scallop moored at a lower density (60 scallops/tray) and at a depth of 5 m also presented a high mortality rate in September (86.67%), which forced us to terminate the culture experiment. Growth was similar in both cases during the sampling of both depths until the month of September. Organ growth was similar at the two depths, although it was slightly higher at 5 m depth. The large scallops reared at a density of 40 scallops/tray exhibited a similar growth in size at both depths, but differed in total weight and organ weight, because these values were higher at 5-m depth. At both depths, the digestive gland decreased in November, whereas the gonad increased. This occurred at all depths and densities owing to the onset of maturation, as seen in the study on the reproductive cycle. Queen scallops moored at a stocking density of 60 individuals/tray had an overall greater growth in size and total weight at both depths, than those stocked at 40 individuals/tray. The gonad, muscle, digestive gland and the remaining tissues behaved similarly. The animals grew quickly during the first winter, reaching the legal size (50 mm in height) in June for queens at a density of 60 and in September for those stocked at 40 individuals/tray. The gonad underwent a sharp rise in growth during the first 3 months, going from 0.21 g in November to 1.30 g in February. From this point on, the gonad weight and the gonad condition index began to decline. Muscle weight rose from 0.69 g to 3.82 g in 1 year, showing a continuous growth throughout the whole year, whereas the muscle condition index fluctuated. The weight of the digestive gland and the remaining tissues and their condition indices grew steadily throughout the whole year. In general mortality was high, particularly in September, probably because the high temperatures. Based on the results, the following

conclusions may be drawn: From the time the culture started, the *Mimachlamys varia* scallops moored at high densities (100 scallops/tray) and at 5-m depth had a higher growth in all the parameters sampled than those moored at 15 m, however the latter specimens did not show any mortality until November (8%). In the trays moored at 15 m, the animals exhibited a reduction in growth from September to November, and a drop in flesh weight. The *Mimachlamys varia* scallops moored at lower densities (40 scallops/tray) grew at a similar rate at both depths. In contrast, the total weight and organ weight were higher at 5-m depth. At both depths the digestive gland decreased in November whereas the gonad underwent an increase. Growth in *Mimachlamys varia* is greater at a density of 40 individuals/tray and at 5-m depth below the bottom. Growth in the queen scallops was greater at a density of 60 individuals/tray and at both depths. The growth of this species does not appear to be affected by depth, unlike in *Mimachlamys varia*.

THE USE OF DIFFERENT GROW-OUT METHODS IN THE CULTURE OF *PECTEN MAXIMUS*, *MIMACHLAMYS VARIA* AND *AEQUIPECTEN OPERCULARIS* IN MÁLAGA (SPAIN). Juana Cano,¹ Jesús Campos² and Francisco J. López.¹ ¹Centro Oceanográfico de Málaga, Instituto Español de Oceanografía, PO Box 285, 29640 Fuengirola (Málaga), Spain; ²Centro Oceanográfico de A Coruña, Instituto Español de Oceanografía, PO Box 130, 15080 A Coruña, Spain.

In 2001 studies were conducted on the maximum time pectinid spat should remain in the collectors with a view to examine the growth and survival of three scallop species (*Pecten maximus*, *Mimachlamys varia* and *Aequipecten opercularis*) (Campos & Cano 2003a and 2003b). Moreover, in 2002, when the spat were detached from the collectors, we found a large quantity of *Mimachlamys varia* seed <0.5 mm in size which would filter through the mesh of the quarters used to grow-out small spat and get lost. We decided to moor the spat in clean collector bags to prevent losses, because this scallop spat quickly resettles, using its byssus threads as an attachment base. With the results obtained from previous studies and within the framework of Project ACU00-008-C3-1 financed by the INIA, we decided to carry out this research work to determine the feasibility of other systems as an alternative to trays to be used in pectinid culture. Spat were procured from

collectors moored between January and July and removed in September 2003. This year we decided to moor the three species of scallops, *Pecten maximus*, *Mimachlamys varia* and *Aequipecten opercularis* removed from the collectors, in trays and bags similar to the collectors used to procure the spat, and carry out a comparison of the results. Monitoring of the spat began after removal and continued until December 2004, when the last sampling was taken. Another grow-out experiment was performed using *Mimachlamys varia* spat, taking advantage of its natural attachment mechanism by means of the byssus. Scallops were hung using a rope covered with a self-digesting net, similar to the kind used in mussel culture. During the sampling we recorded the size (height in mm) and survival (number of live specimens in each sampling). Great scallop spat were moored after being sorted into large (27.12 ± 5.32 mm) and small (17.20 ± 5.32 mm) sizes. Initial stocking densities in the trays consisted of 60 large and 200 small seed of great scallop/tray and in bags containing 100 large great scallops and 200 small great scallops/bag. *Mimachlamys varia* spat were separated into large (27.32 ± 2.34 mm) and small (23.40 ± 2.77 mm) sizes. These scallops were cultured in trays at a stocking density of 80 large scallops/tray and in bags containing 275 large specimens and 300 small scallops per bag. Large queen scallops were grown-out in trays at a stocking density of 80 queens per tray and in bags containing 100 specimens per bag. After 15 months of culture, the small-sized great scallops reached a height of 79.64 ± 6.18 mm and the large specimens, 81.63 ± 6.30 mm. In the trays moored in September a slower growth rate was observed from October to December. It seems that after sorting, the differences in size tend to decrease over time and level off at the end of the culture period. There were no mortalities for the first 12 months, whereas the last 3 months exhibited a very low mortality rate (2%). The small specimens of the great scallop cultured in bags attained a height of 57.91 ± 4.12 mm and the large specimens measured 62.50 ± 3.22 mm, after 15 months of culture. Mortality was very high at the end of the culture, 68% and 66% for large and small specimens respectively. The large *Mimachlamys varia* scallops moored in trays had reached a height of 49.37 ± 2.12 mm in April 2004, exceeding the commercial size of 40 mm. In December 2004, the date of the last sampling, they measured 60 ± 5.31 mm. The mortality rate was 12%. Growth in bags was very good, with the large specimens having attained a size of 43.02 ± 3.91 mm in April 2004, which means that they reached commercial size in 6 months. After 15 months they measured 56.66 ± 4.27 mm and total mortality was 8.72% at the end of the culture. The small specimens of this species took slightly longer to reach commercial size (9 months) and their mortality was 10%. The scallops were hung on ropes and placed in bags to be able to observe the number of specimens that settled. Settlement was only average—just half of the scallops settled on the ropes. In contrast, the growth of the animals that did attach to the ropes was good, and the mean height of the scallops hung on ropes increased from 12.83 ± 2.27 mm to 48.25 ± 3.12 mm. The scallops grew 35.42 mm in 11 months. In

the floating trays there was no mortality except in the spat removed in August, during which time it reached practically 100%, probably owing to the great fluctuations in temperature that were recorded. The spat grew quickly in the trays during the first winter, attaining a height of 40 ± 2.51 mm in March. In summer the growth rate started to diminish, with the average height in November being 52 ± 4.82 mm. Starting in October, mortality decreased and the spat grew rapidly in the bags. Average spat height went from 16.6 ± 3.47 mm when they were detached in September to $28.8 \text{ mm} \pm 3.76$ in January, with a mortality of 37.5%. The three species grew more rapidly in the trays than in the bags, although it is still too early to draw conclusions. In any case, the bags are easier to handle and less expensive than the trays and spat can probably be held there for a period of time before being transferred to tray culture. When the trays and bags containing *Mimachlamys varia* and *Aequipecten opercularis* were removed in November, 2003, a high mortality was detected, coinciding with a high mortality of adult *Mimachlamys varia* being cultured in other trays. This mortality might be attributable to some type of viral or bacterial infection. There also could have been a problem with handling as the spat might have been out of the water for too long, in addition to the high temperatures during the month of September when the scallop spat was being removed. The scallops of *Mimachlamys varia* that did survive underwent excellent growth and presented a very low mortality rate. The prospects for the use of collector bags and rope hanging techniques in scallop culture look very promising. The hanging technique needs to be improved, as it is a process that requires skill. Also a longer-lasting mesh should probably be considered for use.

SCALLOP SPAT PRODUCTION IN NORWAY—IS LAND-BASED NURSERY NEEDED AS AN INTERMEDIATE STEP BETWEEN HATCHERY AND SEA? Gyda Christophersen and Thorolf Magnesen. Centre for Studies of Environment and Resources, University of Bergen, PO Box 7800, 5020 Bergen, Norway

Traditionally small *Pecten maximus* spat (post-larvae) of approximately 2-mm shell height have been directly transferred from the hatchery to sea-based nursery. Post larvae are obtainable on a year round basis, whereas spat production depends on environmental conditions in the sea. Spat size and timing of deployment are found to be determining factors to ensure high spat yield (Grecian et al. 2000, 2003, Christophersen & Magnesen 2001, Rupp et al. 2005), and the growth season in Norwegian waters is limited by

low sea temperature in the spring (5°C to 10°C). Strategies to extend the production period have been pursued by acclimating small spat to colder water (Christophersen & Magnesen 2001) and by using solar heated “poll” as water source to land-based indoor nursery (Christophersen & Lie 2003). The occurrence of potential predators, which can settle inside the equipment and fouling are other factors that may impair the yield (Louro et al. in press). During the warm water season deployment of spat may coincide with the settlement of starfish larvae, and presence of *Asterias rubens* have caused heavy losses. With the aim to improve survival of spat deployed to the sea, the scallop hatchery in Norway (Scalpro AS) built an outdoor land-based raceway nursery, as an intermediate step between the growth to 2 mm in the hatchery and final nursery growth in the sea from 6–10 mm to 15–20 mm. Different trials have been undertaken to investigate the performance of spat in order to evaluate the usefulness of the new land-based nursery. The spat were obtained from *P. maximus* brood-stock collected from natural scallop beds in Hordaland County, western Norway, which was conditioned and induced to spawn according to standard methods at Scalpro AS. Small spat (1–7 mm) were transferred from indoor conditions in the hatchery to an outdoor land-based nursery after settlement either on downwelling screens or on collector bags. Spat that had settled on screens were relayed onto trays, whereas the collector bags with attached spat were transferred directly to the nursery. Growth of spat of different size at transfer was compared, as were spat grown in the land-based and the sea-based nursery. The spat allowed to settle on collector bags had been exposed to different tank conditions (light, water-circulation, bag color) and the subsequent yields were examined. The land-based nursery was of a flow-through raceway type with 10 parallel raceways of length 10 m, width 0.6 m and depth 0.8 m, which could potentially hold 7 million small spat. Seawater was filtered through a drum filter of 100-µm mesh and supplied the nursery at a pumping rate of 6 m³ per minute, equivalent to a velocity of 2 cm per second. The experimental nursery period was from May to September when the sea temperature was 7°C to 19°C. Preliminary results showed that growth in the land-based nursery was equal to growth in the sea considering spat that retained on 6 mm mesh after 6 and 9 weeks growth. The relative shell-height growth was size dependent and varied from 1.5% to 4.2 % per day. On land, 85 % of spat of initial size 1.4 and 1.8 mm survived, whereas survival of spat of initial size 3, 5 and 7 mm was 78%, 88% and 91% respectively. Survival of the slowest growing fractions was superior in the land-based nursery. The yield of spat >5 mm from collector bags varied from 46 to 2,780 per bag. In addition a large portion of spat were recovered from the bottom of the raceway. No significant differences in spat yield were found between the different pre-transfer treatments. A higher yield related to competent larvae was obtained from screens than from collector bags, and the settlement on each collector bag was too low to utilize the maximum capacity of the raceway. Without

improving the settlement per bag, the production in trays seemed to be the most viable method. Only light fouling (clogging) was observed on the trays in the raceway and starfish larvae rarely occurred. Thus it was shown that fouling organisms and predators were efficiently removed by the filter at the water intake to the raceway and that survival was improved in the system. By securing favorable growth conditions for the slow growing individuals the final spat yield may be enhanced. Maintenance of trays from the land-based nursery was less labor intensive than of trays from the sea-based nursery, but the capital cost of the land-based nursery was higher. Nevertheless, the cost difference could be compensated by the higher survival in the land-based nursery, and taken into consideration, the increased survival by deploying larger spat to sea; the use of an intermediate nursery seems advantageous.

IN ÎLES-DE-LA-MADELEINE (QUÉBEC, CANADA), CAN SEA SCALLOP (*PLACOPECTEN MAGELLANICUS*) JUVENILE LOSSES BE REDUCED DURING THE YEAR THEY STAY ON COLLECTORS TO REACH AN APPROPRIATE SIZE FOR HANDLING? Georges Cliche,¹ Carole Cyr¹ and Denyse Hébert.² ¹Ministère de l'Agriculture, des Pêcheries et de l'Alimentation du Québec, Direction de la recherche scientifique et technique, 184 Chemin Principal, Cap-aux-Meules, P.Q., Canada, G4T 1C6; ²Pétoncles 2000, 55 route 199, Fatima, Canada G4T 2H6.

In Îles-de-la-Madeleine (Québec, Canada), scallop producers have to deal with very high spat mortalities (>70%) during the year spat has to stay on collectors to reach an appropriate size to be

handled and put into pearl nets for intermediate culture. Usually collectors are immersed at the end of September. Recuperation and cleaning operations start in the middle of September of the following year and last until the end of November. Mortality occurs mainly between the middle of August and the end of November. Main factors pointed out to explain this phenomenon are related to the overabundance of organisms (scallop and undesirable species) inside the collectors. As time goes on, packing of organisms on the bottom of the collector bag increases inducing very high densities of animals and their mortality. On the other hand, as organisms grow, weight of collectors increases. Longlines crash on the sea bottom and collectors drag the bottom contributing to additional mortality. Recuperation and cleaning of collectors before the middle of August, present 3 major problems: (1) scallops are still very small at that time (around 5 mm); (2) air temperatures are relatively high to handle sea scallops and (3) intermediate culture is realized in lagoons where heavy mussel fouling on the pearl nets may take place until the beginning of September. Discussions with Japanese scallop producers in 2002 brought us to test their strategy and to put very small scallops in intermediate culture at the beginning of August before high mortality affect scallop spat on commercial collectors. Because it was very important to develop a production strategy usable by industry, commercial scallop producers were associated with all steps of the experimental project. Undesirable species, mainly blue mussel (*Mytilus edulis*) and hiatellas (*Hiatella arctica*), are very abundant on collectors and sorting is required when collectors are cleaned. It is essential for producers to use a mechanical sorting machine able to handle and to sort large numbers of animals. The first challenge with the new strategy was to know if mechanical sorting was possible and effective with very small animals. A preliminary essay permitted to conclude that it was possible. For experimental trials, manual sieves were used but these sieves were adaptable to the mechanical sorting machine. In the preliminary essay of 2003, scallops were lost because adjustments of sieves were not optimum. Improvements were made in 2004 and the recuperation rate improved. Japanese producers, after having sorted manually, put small scallops in large pearl nets (50 cm × 50 cm) with a mesh of 1 mm at very high densities (up to 10,000/pearl net) and let animals grow for 1 to 2 weeks before reducing densities. They usually manipulate rearing structures many times to finally bring scallops to optimal densities for suspension culture. To reduce the number of rearing structures, we also decided to use initially high densities in a standard pearl net doubled with 1-mm mesh size net. However, to lower the manpower costs associated with reduction of densities, we decided to test 2 strategies:

- to keep the animal at high density (around 1,500/pearl net) for 2 to 3 weeks, then
- to reduce densities and to test 4 densities (200, 300, 400 and 500 scallops/pearl net 2 mm mesh size) and finally 1 month later to reduce the density to 115 scallops/pearl net for the rest of the

intermediate culture period to leave animals at high densities (around 1,500/pearl net) for 1.5 months and then to reduce densities to 115 scallops/pearl net.

Keeping in mind possible fouling problems with mussels on rearing structures in the lagoon, strategy 1 was also tested in the open sea on a site where mussel fouling could be low. On the 20 collectors used for experimental essay, the number of living scallops was estimated to be 28 180 scallops and their mean size was 4.5 ± 0.9 mm. From this number, sorting permitted to recuperate and to put in pearl nets at high density, 15,051 scallops (53.4%). When pearl nets were recovered for strategy 1, 2 weeks later, 93, 3% of scallops were alive, or 49.9% of number originally present on collectors. Their mean size was 6.8 ± 1.3 mm. Survival rates obtained after 1 month in pearl nets at 4 densities were very high varying between 91% and 96.5% for the pearl nets immersed in the lagoon and 91% and 93% for the ones immersed in the open sea. There was no difference between survivals obtained with different densities. Growth rates obtained with the strategy 1 were particularly interesting. In the lagoon, daily growth was 0.29 mm/day and in the open sea, 0.27 mm/day. No difference was observed between growth rates with different densities. During the same period, the growth rate of scallops left on collectors in the open sea was 0.08 mm/day. So at the middle of September, the size of scallops on commercial collectors in the open sea was 8.5 mm. The size obtained at the same time with strategy 1 was 17 mm and with strategy 2, 13 mm. With strategy 2, the recuperation rate obtained 48 days after immersion in the lagoon at the density of 1,500 scallops/pearl net was of 89% (48% of initial number found on collectors) and daily growth was of 0.18 mm/day. Mussel fouling was almost inexistent on the pearl nets and never represented a problem. The main problem associated with the mussels was that some mussels were put in pearl nets with scallops because sorting could not be totally effective. Even if the number of mussels was very low, many scallops were found trapped in byssus only 2 weeks after being put in the pearl nets and higher mortality and lower growth were associated with agglomerations of scallops and mussels. In 2004 new trials were realized. Recuperation rates were improved by 20% and the results on growth and survival were comparable with the ones of 2003. Mussel fouling was still negligible on rearing structures. This new strategy has permitted to increase recuperation rate of scallops present on commercial collectors. Treating collectors before high mortality that starts at mid August has at least doubled the recuperation rate. Sorting of small scallops at the beginning of August is possible and effective. Even if operations took place in a period of the year where air temperature may be over 20 °C, survival rates were very high. Increase in size is also very interesting because young scallops put in pearl nets earlier in the season are approximately 10-mm larger than the ones left on collectors at the middle of September. Usually scallops are seeded in May and June of the following year and this increase in length represents an advantage to improve the resistance of

scallops to predators. Scallop producers plan to realize in 2005 a pilot project to confirm the interest of this new strategy on a commercial scale.

MANAGEMENT OF COMMERCIAL SCALLOPS IN THE BASS STRAIT CENTRAL ZONE SCALLOP FISHERY, AUSTRALIA. Elizabeth Colterrell and David Johnson. Australian Fisheries Management Authority, Box 7051, Canberra BC ACT 2610.

Commercial scallops (*Pecten fumatus*) have been fished in the waters of Bass Strait since the 1970s, as boats explored new grounds. The major fishing grounds off Lakes Entrance in eastern Victoria, the northern coast of Tasmania, King Island in western Bass Strait and the Furneaux Island group in eastern Bass Strait have subsequently been fished heavily, with fishing activity peaking in the early 1980s at a total catch of nearly 12,000 tons shell weight (Young & Martin 1989, Zacharin 1990). At this time fishing was virtually unregulated and there was a huge increase in fishing effort and expansion of the fleet, with a trebling of effort in the fishery in the 2 years from 1981 to 1983 (Zacharin 1990). Three fisheries for commercial scallops, managed by 3 management agencies (the Victorian Government, Tasmanian Government and Commonwealth Government), evolved though all indications are that it is a single stock of scallops. Each management agency has different governing legislation and has a different management regime (later). The overall fishery in Bass Strait has been characterized by a series of booms and busts. There was a major decline in scallop catches in 1985 to 1987, which led to the closure of the Tasmanian fishing grounds from 1988. The Commonwealth Central Zone was closed in 1990 for 1 year because of low stock levels. The Tasmanian grounds reopened to fishing in 1995 but were closed again in 1997 and 2000 to 2002. The Central Zone was closed again in 1999 following dramatic declines in catch from 1997 to 1998 and did not reopen to commercial fishing until 2002. Virtually no fishing took place in that year. In 2002 the Commonwealth legislated that at least two areas of the Central Zone fishery (one in the west and one in the east) be closed to fishing each season to minimize the probability of recruitment overfishing. Since that time an area off Flinders Island in the east of the fishery has been closed to fishing. This closure is reviewed annually in the light of available information on stock status. Additional measures to protect spat and juveniles from the impacts of fishing were also implemented; a bed is not opened to fishing unless less than 20% of commercial scallops in the bed are above the minimum size limit.

The most important aspects of the various spatial management regimes used by each management agency were summarized by Haddon et al. (2004) as follows:

Tasmania: Most scallop beds closed, with small areas open, with a flexible maximum catch allocation per quota unit within the fishery and size and trashing rate limits;

Commonwealth: Most scallop beds open, with small areas closed, with an effective total allowable catch (TAC) and size and trashing rate limits;

Victoria: All beds open every year with an implied TAC. There is scope for temporal closures depending on condition and size of scallops.

One of the major challenges for fisheries management in regards to Bass Strait scallops is management of a single stock by multiple jurisdictions. The Australian Fisheries Management Authority (AFMA) was established under the Fisheries Administration Act 1991 and manages fisheries under the Fisheries Management Act 1991 (the FMA). AFMA is the Commonwealth statutory authority responsible for ensuring the sustainable use and efficient management of Commonwealth fishery resources on behalf of the Australian community and key stakeholders.

The FMA requires AFMA to pursue 5 objectives. In brief these are:

- efficient and cost-effective fisheries management
- ecologically sustainable development
- economic efficiency
- accountability
- cost recovery

AFMA must also seek to ensure that Commonwealth fish stocks are not over-exploited. AFMA's management philosophy involves a partnership approach to the management of marine resources under its jurisdiction. This approach provides opportunities for stakeholders to have input into the management process through various management advisory committees or MACs. AFMA's board of directors makes decisions on fisheries management issues based on advice from MACs, AFMA staff and other special committees. Scientific surveys have been conducted in the Central Zone since 2000. These surveys have provided information on scallop size and abundance, and have been considered by the MAC and the AFMA board when recommending fishery closures and TACs. The fishery is currently considered to be overfished (Bureau of Rural Sciences, 2003). At present there is an area closed off Flinders Island. This contains the only known bed of commercial-sized spawning scallops in the Central Zone. The most recent scientific information (M. Haddon, pers. comm.) indicates that there may be fewer than 1,000 tons of scallops present in the survey area. Scallop operators are facing some marketing challenges. These relate mainly to continuity of supply of fresh product to domestic and export markets and have been exacerbated by competition with cheaper imported product. There are also issues of overcapitalization in the fishery. Whereas the mechanism for structural adjustment exists under the management plan for the fishery, the depressed economic situation in the fishery means that there is no money available for this to occur.

The major challenge for AFMA is how to ensure an ongoing, sustainable, resource while providing an economic return to operators. Other challenges are as follows:

- Integrating spatial management and conservation objectives across jurisdictional boundaries
- Developing decision rules, e.g. for alternative season dates
- Cost-effective gathering of data on the fishery and stocks over large areas

IMPROVING QUALITY OF SEA SCALLOP SPAT COLLECTION BY A MORE ACCURATE DETERMINATION OF THE IMMERSION PERIOD OF COLLECTORS IN ÎLES-DE-LA-MADELEINE, QUÉBEC, CANADA. Carole Cyr,¹ Georges Cliche,¹ Gaston Desrosiers² and Bruno Myrand.¹ ¹Station maricole des Îles-de-la-Madeleine, Ministère de l'Agriculture, des Pêcheries et de l'Alimentation du Québec, 184 Chemin Principal, Cap-aux-Meules, G4T 1C6; ²Institut des sciences de la mer de Rimouski (Ismer), Rimouski, Québec, G5L 3A1.

Overabundant settlement of undesirable organisms on scallop collectors can negatively affect survival rate and growth of young scallops, increase time to handle and clean collectors, slow sorting operations in the plant and increase production costs. In 1998, predation by starfish (*Asterias vulgaris*) inside collectors resulted in high spat mortality. In 2001, overabundance of bivalves *Mytilus edulis* and *Hiatella arctica* in collectors has caused high mortalities. Many collectors dragged the sea bottom because the weight of long lines was too high. A study done in 2003 to 2004 near a commercial site of spat collection, located east of Îles-de-la-Madeleine (Québec, Canada), aimed to evaluate if it were possible to target more accurately the immersion period of collectors to reduce abundance of undesirable species and maintain high collection of scallop spat. Specific objectives were (1) to determine the spawning period of sea scallops and (2) to evaluate if larval monitoring and/or postlarval monitoring for peak settlement could be used as tools to determine an optimal immersion period of spat. The sea scallop spawning (length >90 mm) was investigated by monitoring the gonadosomatic index (GSI). This index was calculated as the percent ratio between the wet weight of gonad and the one of remaining soft parts. Weekly samples of 20 adult scallops (for a ratio of 50% female and 50% male) were collected by

dredging at the depth of 28–30 m, between the end of July and the middle of September on the Chaîne-de-la-Passe (fishing area) and on the Fond du Sud-Ouest (natural bed closed to fishing since 1991). To determine larval densities, a sample of known volume of seawater was pumped between 2 and 8 m off the bottom at three sites. The larval monitoring was realized between July 4 and October 29. Larvae of sea scallops (*Placopecten magellanicus*) and 4 undesirable species (molluscs: *Mytilus edulis*, *Hiatella arctica*, *Anomia* spp. and echinoderm: *Asterias vulgaris*) was identified and counted. A random sub-sample of 30 larvae of each species was also measured under a stereomicroscope analyzer Bioquant IV Leica (×100). Spat collection monitoring (2nd tool): Recruitment of newly settled sea scallop and undesirable spat species was estimated using artificial collectors immersed for 7-day intervals during the scallop postlarval settlement period. Collectors were made of four Netron sections inside a 2-mm mesh spat-collecting bag. Collectors were suspended at 2 m off the bottom. Collectors were immersed weekly at three sites (water depth from 30–32 m), for 11 consecutive weeks, starting on August 19. A week after deployment, collectors were retrieved and cleaned over a 250-µm mesh sieve. The content of collectors was preserved in 95% ethanol. Sea scallops and four undesirable spat species found on collectors were counted. A random sub-sample of 30 specimens of each species was also measured. In 2004, to verify loss of spat during collection, sleeves of 250-µm mesh were gently placed over the collectors underwater before their retrieval. Other spat collectors made as described earlier, were placed in the commercial spat collection site at 2 m off the bottom. Five collectors were deployed weekly (water depth from 30–32 m), for 6 consecutive weeks, starting September 15. In December 6, collectors were retrieved and cleaned. The content of each collector was preserved in 95% ethanol and analyzed as described earlier. The GSI monitoring showed that adult scallops initiated spawning by August 26 on two sites sampled. Spawning was completed on September 15. Larvae of mussels were most abundant. Highest larval density of 15.96 larvae/L (>200-µm shell height) was recorded on September 2. Other species had densities lower than mussels. We observed a peak of larvae of *Anomias* on October 20 (2.71/L), of *Hiatellas* on October 1 (0.45/L) and of sea scallop on October 29 (0.10/L). Of the undesirable organisms, mussel was the most abundant. Highest density (1148 spats/collector) was observed on August 26. Other molluscs in order of decreasing abundance included: sea scallop (465/collector on October 20), hiatellas (354/collector on October 26) and anomias (47/collector on September 8). Starfish, a major predator of scallop spat, was only present in low numbers (between 0.33 and 6/collector) except on September 22 with 26/collector (diameter between 0.8 and 1 mm). In 2004, use of divers to recuperate a sub sample of collectors inside bags with mesh of 250 µm showed that there was no loss of organisms when collectors were recovered directly from the boat. We can observe a peak of scallops in collectors immersed on October 7 (6147/collector). Highest densities of mussels, *Hiatellas* and *Anomias* were found on col-

Figure 1. A) (First tool) Number of larvae per liter pumped between 2 and 8 meters off the bottom \pm ecartype (scale for mussels at right), B) (Second tool) Number of postlarvae per collector immersed one week \pm ecartype (scale for mussels at right). Collectors were immersed and retrieved a week later. C) Number of spats per collector immersed to different periods \pm ecartype. Collectors were retrieved on December 6, 2003.

lectors immersed on September 15 with respectively 2727, 5154 and 3760/collector. Collectors immersed 8 weeks after the beginning of spawning of sea scallop (October 21) contained 3281 scallops, 532 mussels, 683 *Hiatellas*, 165 *Anomias*. Starfishes were found in low numbers on collectors in 2003 (only 1 on September 15 and October 13). Monitoring of larval abundances permit to identify peak of larvae >200-µm but aside from mussel, it does not seem to have a relation between larval abundance and spat settlement in collectors. For mussels, the curves present the same tendency to decrease with time (Fig. 1A and 1C). Scallop larvae were always the less abundant, whereas this species was always the one most abundant on collectors (Fig. 1A and 1C). With results of mussel larval monitoring, it would have been possible to recommend to scallop growers to start immersion of their collectors on September 23. The number of mussels would have been reduced by half still with a good scallop collection rate. The weekly monitoring of spat collection is a good tool to identify peak of settlement. The high collecting rates of mussels and hiatellas were observed at the end of August and at the beginning of September (Fig. 1B and 1C). Results of weekly monitoring of spat collection would not have been useful to reduce the number of mussels and hiatellas on commercial collectors deployed 3 weeks after the scallop spawning. Some years, the first peak of the collection of mussels and hiatellas may be later in September. When it happens, weekly spat monitoring could be a useful tool to identify the prob-

lem and to recommend to producers to slightly delay the immersion of scallop spat collectors. Another useful utilization of these results is the possibility of knowing if there is still interest in immersing commercial collectors late in the season. Meteorological conditions are particularly rough in fall and it is not always possible for producers to immerse their collectors in a short period of time. Aside from mussel, weekly monitoring seems to underestimate the collecting success of scallop, *Hiatella* and *Anomia*. A possible explanation of low collecting success of certain species is that collectors immersed for 1 week are not fully effective for certain species possibly because conditioning of collecting substrate (bacterial biofilm) is not optimal. Other experimental works will be necessary to validate this hypothesis.

VIDEO CAMERA SURVEY OF WILD SEA SCALLOP BEDS VERSUS ENHANCED BEDS IN THE SOUTHERN GULF OF ST. LAWRENCE. Leslie-Anne Davidson and Monique Niles, Dept of Fisheries and Oceans, Leslie-Anne Davidson, Dept of Fish. and Oceans, 343 Université Ave, Moncton, N.B. E1C 9B6 Canada.

In the southern Gulf of St. Lawrence, sea scallops (*Placopecten magellanicus*) can be found on various beds. This resource has been commercially fished since the turn of the century, and in the

Figure 1. The density of adult and juvenile scallops on the enhanced and fished sites.

last few years the scallop landings have decreased. The Maritime Fishermen's Union (MFU) in New Brunswick Canada has been involved in a scallop enhancement project since 1996. However an effective enhancement program has only been in place since 2000. This study attempts to evaluate the success of the enhancement activities by comparing enhanced sites to fished sites. In October 2003, a study was launched to compare the scallop density of enhanced beds to commercially fished beds. An underwater video camera mounted on a sled was towed from a research vessel over the bottom at a speed of 1 knot. Other equipment required for the study included a television, digital recorder, cassettes, global positioning system (GPS) and a computer. The camera was oriented to video tape the marine bottom, and the geographical position was recorded using a GPS overlay. Each site was video taped for 3 to 4 hours. Video recordings were analyzed to determine the density of the adult scallops, the swimming juvenile scallops, sea stars, crabs, lobsters, other species and bottom type. The survey was conducted over three enhanced beds and two commercial fished beds (Table 1).

TABLE 1.
Scallop beds evaluated using video.

Site	Date Seeded	Area Evaluated (m ²)	Date Evaluated
Fishing sites: Northumberland Strait	N/A	7752	October 1, 2003
Baie des Chaleurs	N/A	8640	October 8, 2003
Enhancement sites: Northumberland Strait	May 2003	10932	October 2, 2003
Baie des Chaleurs	May 2002	3372	October 7, 2003
Baie des Chaleurs	May 2003	7992	October 7, 2003

The adult scallop density on the enhanced site that was seeded 18 months before the video survey was 1.7 to 2.7 times higher than those on the fished sites. Conversely, less adult scallops were recorded on the enhanced sites that were seeded only 6 months prior to the survey (Fig. 1). The young swimming juvenile scallops were observed on all sites except on the fished site in Baie des Chaleurs (some juvenile scallop density values are too low to be seen on the graph). The highest density of juvenile scallops was observed on the site seeded 18 months before the video survey. The scallops seeded 6 months before the survey are possibly too small to be observed by the video camera. Nadeau and Giguère (2000) reported that density assessments using the video camera evaluation are only 75% accurate. However, positive results of the enhancement project seem to be measurable 18 months after the seeding. Nonetheless, the scallop density on the enhanced and fished sites in the southern Gulf of St. Lawrence is low relative to enhanced beds in other parts the world. Hébert and Nadeau (2002) reported that in New Zealand the aim is to harvest an enhancement site when the density has reached to 1 scallops/m².

Data regarding the density of all species at the study sites indicated that seastars are found in higher numbers on the enhanced sites than the fished sites (Fig. 2). Because the seastars prey

Figure 2. The density of all species on the enhanced and fished sites.

on scallops their presence may have a negative impact on the success of the project.

BREEDING SEASON OF *CHLAMYS VARIA* (L.) IN SPAIN.

J. P. De la Roche,¹ A. Louro,¹ O. García,² G. Hernandez² and G. Román.¹

¹Instituto Español de Oceanografía, Centro Oceanográfico de A Coruña, P.O. Box 130, 15080, A Coruña, Spain;

²Universidad de Santiago de Compostela, Instituto de Acuicultura, Departamento de Bioquímica y Biología Molecular, 15782 Santiago de Compostela, Spain.

The black scallop *Chlamys varia* is being considered as a candidate for aquaculture in Spain. There are no dense local populations of this species in Spain, and no commercial fishery has been developed. Two areas of Spain show promising conditions for culture of this species; in Galicia (NW Spain, Atlantic Ocean) the black scallop was formerly fished, but nowadays landings are no longer recorded and supply of spat depends on hatchery production. In Málaga (South Mediterranean), black scallops are not commercialized, in spite of the abundant settlement found to occur in collectors. Settlement in collectors and spawning in hatcheries are directly linked to the breeding cycles, therefore a detailed knowledge of the cycle in both areas is important for aquaculture management. The breeding cycle of *C. varia* has been previously reported for France, Isle of Man, Ireland and Galicia. As a rule, the breeding cycle shows a bimodal pattern. The timing of the cycle varies with latitude, with the breeding season taking place later in northern populations. Reddiah (1962) recorded spawning in Isle of Man in June and November, whereas Burnell (1983) reported spawning in June and August on the west coast of Ireland. In French waters spawning takes place in May and September (Lubet 1959, Lucas 1965, Shafee & Lucas 1982). According to Parada et al. (1993) in Galicia *C. varia* spawns in March, May and August. There are no reports available about the breeding season of *C. varia* in Málaga. According to previous reports, *C. varia* is a protandric consecutive hermaphrodite in which the gender ratio is related to age/size, with a higher percentage of females being recorded in older/larger scallops. Gonad color is variable but is often a whitish-cream color, regardless of gender, although sometimes a yellow gonad has been recorded and identified as female (Lubet 1959, Lucas, 1965). The objectives of this study are to compare the breeding cycle and the sexual behavior of populations of *C. varia* from Galicia and Málaga. Hatchery produced spat of *C. varia* (Galicia) and spat settled on collectors in Málaga were main-

tained in cages suspended from a raft (Ría de Arousa, Galicia) and from a long-line (Marbella, Málaga) respectively. In Galicia, the spat was produced in the hatchery in June year 0, transported to sea in autumn year 0, and maintained in intermediate culture I and II (Román et al. 2003) until February year 2 (mean size 42.3 ± 4.7 mm, 21 months old), when sampling for studies on breeding cycle began. In Málaga, collectors were deployed in April year 0 and detached in November year 0. Sampling began in January year 1 (mean size 36.1 ± 2.8 mm, 11 months old). In both cases, sampling was carried out fortnightly. Thirty scallops were measured, the gonads removed and the dry weight (100°C , 24 h) obtained. Gonad color was recorded and gender determined by microscope analysis of gonad smears. The breeding season in Galicia starts in spring and goes on until the end of summer. As in northern populations, two main breeding periods were observed, with a maximum recorded between April and May. As a consequence of spawning in this period minimum values were observed at the end of May. After a rapid recovery a new maximum was reached in mid-June followed by a slow decrease in gonad weight until minimum values were reached in September, indicating the onset of the resting period. A higher proportion of males was recorded, although a slight increase in the proportion of females was recorded as the breeding season proceeded. The gender ratio (F/M) was always <0.5 between February to May (first spawning) but increased to 0.7 in the second period. Color was not useful for distinguishing the gender, because both male and female gonads varied in color between white and cream. However, some females bore yellow gonad. In Málaga the breeding season, which began when scallops were 9 months old, extended from middle winter to the end of summer. During this time continuous reproductive activity was observed with probably five spawning events. The breeding period ended by mid August. In this population, the mean value of the F/M ratio was 1.1, and the color of the gonad was useful for differentiating between males and females, because males always bore white gonad whereas the female gonad was always yellow or orange. In Galicia the breeding period was found to be similar to that recorded in other northern populations, except that gonad

Figure 1. Breeding season in two populations of *C. varia* in Spain.

development began and ended earlier, whereas in Málaga the reproductive cycle began earlier and ended earlier and involved more spawning events than any other cycle described for this species. The two populations differed in terms of the gender ratio, gonad coloration and timing of breeding which may, to some extent, be related to environmental factors (temperature, food availability, photoperiod) associated with latitude. The Galician population behaved in the same way as the northern populations, whereas the population from Málaga showed distinctive and exclusive behavior never previously recorded in other populations.

SCALLOP CULTURE IN AUSTRALIA—SCOPING STUDIES, DEVELOPMENT AND REALITY. Mike Dredge. 40 Hall Road Narangba, 4504, Queensland, Australia

Scallop culture is a major form of aquaculture: one with global production now in the order of 2 million tons per year. Whereas scallop culture hasn't developed into a viable industry in Australia thus far, one Australian species, *Amusium balloti*, has growth and market characteristics that offer promise for scallop aquaculture. A detailed feasibility study on scallop aquaculture, incorporating biological, marketing and economic reviews and modeling was funded by FRDC and completed by a diverse and experienced technical working group in 2002. The economic models suggested profitability under almost all operating scenarios. Two Australian companies have attempted to develop scallop culture based upon *A. balloti* during the past 5 years. One of these companies was set up as a direct result of the feasibility study's output and the other has used development procedures remarkably similar to those described in the feasibility study. Both companies have struggled to develop their operations into economically viable businesses thus

far. Developmental delays can be attributed to both organizational and technical limitations. One company, based in Western Australia, has fully developed infrastructure and authorization, but has had problems with consistency of spat supply. The second, Queensland-based company has experienced a series of delays caused by authorization processes and staff turnover. Some of these delays can be attributed to the company's failure to fully understand government process and legislation. At the same time, government procedures for establishing marine aquaculture in a form that required exclusive access of the seabed and water above it were very poorly defined. Under capitalization and delays in establishing an appropriate organizational structure may have exacerbated the company's problems. There is a good deal to be learnt from this case study. Key points include over-optimism when dealing with technical uncertainty, assumption that private enterprise can develop effective management and new technical skills quickly, budgeting and capitalization of sunrise industries and failure of communication between government agencies responsible for licensing and private venture companies. Companies undertaking new aquaculture operations need to understand government process and need to be sufficiently capitalized to withstand process uncertainty and delay. Above all, they must have a management structure that understands the technicalities and uncertainties of the sunrise industry in question.

POSSIBILITIES AND MYSTERIES IN SCALLOP REPRODUCTION. Arne Duinker. National Institute of Nutrition and Seafood Research (NIFES), PO Box 2029 Sentrum 5804, Bergen, Norway.

The reproduction is an interesting and puzzling part of the biology of *Pecten maximus*.

Some aspects of the main framework are relatively understandable, with clear, testable hypotheses. For the first time in bivalves, oysters have been successfully manipulated with phase-advanced regimes of temperature and photoperiod resulting in a phase advance of the winter restart of gamete development (Chavez-Villalba et al. 2002). A framework for similar manipulation of the annual reproductive cycle has been suggested for *P. maximus* (Duinker 1999; 2002), supported by evidence of a photoperiod effect on early gonad development (Duinker et al. 1999). This kind of experiment would reveal important information about the reproduction of any species of commercially exploited scallops, but still remains to be carried out. Comparative studies with different species would be particularly valuable in this context. Seasonal variation is seen in the larvae yield in hatcheries for *P. maximus*, but short-term variations lead to reduced predictability and increased efforts and number of induced spawnings (pers. comm. T. Magnesen, University of Bergen). These problems seem more complicated and more difficult to study but nonetheless interesting. The variations may be based on several aspects of the cellular physiology in scallop reproduction. Examples may include cycles of

atresia and oocyte growth (Paulet & Boucher 1991) leading to cycles in readiness for spawning and some final preparations for spawning with arrested recruitment of young oocytes and accelerated growth of the remaining cohorts (Duinker 2002). The latter has been observed in *P. maximus* as absence of young cells (Mason 1958, Duinker & Nylund 2002), and Mathieu et al. (1982) showed that oogonial mitosis in mussels was inhibited in mussels prior to spawning by a substance in the mantle tissue. This leads to the question if spawning should be induced in more than one step, with a first stimulus preparing the gonads for spawning and a final stimulus that initiates the actual spawning (Duinker 2002). A similar two-step model was described for the osphradium in *P. maximus* and *Placopecten magellanicus* (Beninger et al. 1995), where a sequence of a “ready” and a “go” cue initiates the accumulation of monoamines and subsequently their release in the gonad, initiating spawning. To increase the predictability in scallop hatcheries, a better understanding of the reproductive biology is needed. Studies of the main framework and the cellular may be necessary. Because research on scallop reproduction is scattered around the world, international cooperation with comparative studies of different species could be beneficial, in particular if involving labs with complementary expertise. One approach could be to compare a species that is relatively easy to spawn, such as the Chilean *Argopecten purpuratus*, with a species that gives more variable results as *P. maximus*.

- INDUSTRY TRIALS OF A SEA SCALLOP DREDGE MODIFIED TO MINIMIZE THE CATCH OF SEA TURTLES.** William D. DuPaul¹, David B. Rudders¹ and Ronald J. Smolowitz². ¹Virginia Sea Grant Marine Advisory Program, Virginia Institute of Marine Science, Gloucester Point, VA 23062, USA; ²Coonamessett Farm, East Falmouth, Massachusetts 02536 USA.
- In response to increasing numbers of sea turtle interactions observed by the sea scallop industry and subsequently corroborated by NMFS observers, a series of 15 experimental cruises were carried out during the summer and early fall of 2003 and summer of 2004 on the continental shelf waters of the mid-Atlantic Bight. The objective of the cruises was to examine the efficacy of a modified commercial sea scallop dredge designed to reduce the bycatch of sea turtles in the sea scallop fishery. The modification consisted of a chain mat spanning the opening of the dredge mouth. The performance of the experimental gear was assessed by comparing a modified dredge fished simultaneously with an unmodified dredge. Results indicate that the modification was successful in eliminating the bycatch of turtles with relatively small reductions in the catch of the target species. A total of 3,078 tows in 277 days at sea was observed during the trials with eight sea turtles captured in the unmodified dredge and none captured in the modified dredge. Of the tows that were sampled by the observers, the modified dredge captured significantly ($P < 0.001$) less scallops relative to the unmodified dredge. On a percentage basis, the modified dredge captured 6.8% less scallops than the unmodified dredge. It is anticipated, however, that the difference in sea scallop catches will decrease over time as industry becomes more familiar with the use of the chain configuration. These cruises demonstrated that a simple modification to the standard sea scallop dredge can be effective in eliminating the incidence of sea turtle bycatch without substantial concomitant reductions in the capture of the target species.
- DISTRIBUTION AND ABUNDANCE OF TWO LION PAW SCALLOP SPECIES (*NODIPECTEN SUBNODOSUS* AND *N. NODOSUS*) IN LATIN AMERICA.** Esteban Félix-Pico,¹ M. Arellano-Martínez,¹ G. Ponce-Díaz² and A. Massó-Rojas³. ¹Centro Interdisciplinario de Ciencias Marinas-Instituto Politécnico Nacional, Apdo. Postal 592, La Paz, B.C.S., C.P. 23000, México; ²Centro de Investigaciones Biológicas del Noroeste, S.C., Apdo. Postal La Paz, B.C.S., C.P. 23000, México; ³Centro de Regional de Investigaciones Pesqueras-Instituto Nacional de la Pesca, Apdo. Postal La Paz, B.C.S., C.P. 23000, México.
- Two species of scallops belong to the genus *Nodipecten*, the Central Atlantic Lion's Paw and East Pacific Lion's Paw scallops, *Nodipecten nodosus* (Linnaeus, 1758) and *Nodipecten subnodosus* (Sowerby I, 1835), although some authors place the East Pacific Lion's Paw scallop in a separate genus, *Lyropecten* (Rombouts, 1991). East Pacific Lion's Paw scallops are found from central Baja California peninsula (28°N) to the Peru (5°S) and into de Gulf

of California in depths of 3–50 m, generally on sand bottom. Distribution is patchy throughout the range and no extensive beds occur, only in Mexico the one largest center of population is in the lagoon Ojo de Liebre, Baja California Sur. The largest and heaviest of the West American tropical species grows up 210 mm. The other one, Central Atlantic Lion's Paw scallops occurred widely throughout the Atlantic coast from South Carolina, USA, Caribbean sea to Brazil and populations support small fisheries. They are large and can reach a shell height of 150 mm (Lodeiros et al. 1999). This study presents the knowledge regarding the fisheries of *Nodipecten* spp. mainly in the Western coast of Mexico and some references in other countries of Latin America. The analysis is based on landings statistics, biomass and population size estimated, and literature reports on the fishery and population dynamics of the scallop. This description approaches topics on the characteristics of the fishery, population changes, catch quotas, prices and local and export markets. In the capture works, approximately 152 people participated, and in the shucking process close to 135 were employed during the season 2004. Most of the catch was taken by divers using semi-autonomous diving. The capture quota per equipment was between 300–400 scallops/day, and each fishing session permits only from two to six pieces of equipment. The biomass was estimated by the swept area method, whereby samples were taken by diving at each 100–250 m and selecting sampling grid at random by CRIP researches. To increase precision in the estimate biomass we made a post-stratification, defined as a new classification of strata, using the observed catch per station. Animals of the *N. submodosus* larger than 80-mm shell height had mature gonads, indicating that sexual maturity is reached at about 1–1.5 year old. The minimum harvest size limit of most measures 140 mm. The population distribution occurs in a patchy pattern and normal densities attain one to two specimens per m² in the beds of the lagoon Ojo de Liebre. The Mexican regulation determined a closed season to protect breeding stocks between September to November, although the fishing period is only 6 months a year (May to July and November to January) (Masó-Rojas et al. 2000). Mexico reported the greatest change from 1995 to 1999, going from 35 t of muscles to an historical maximum of 157 t valued at approximately USD\$2,072,081. The total biomass estimated per year increased during the years 1996 to 1998 from 556–1,600 t. For 1999 the total biomass fell to 1,300 t then later it increased from 770–1,140 t during 1999 to 2004. Overfishing as well as environmental changes, such as those produced by the El Niño 1997 to 1998 have caused changes in its population densities and size structure at the bahía Ojo de Liebre. This descent cannot be attributable to an illegal catch; the most probable cause would be the effects of the El Niño of 1997 to 1998. The landings increased to 100 t of muscles per year from 1996 and remained fairly constant thereafter. The home market for Lion's Paw scallop, though growing, is exported, mainly to the United States. The home markets are La Paz, Los Cabos, Ensenada, Tijuana, Cd. Mexico and the United States. Most scal-

lops are exported (more than 50%) as fresh or blast frozen. The beach price reached values of 150–160 Mexican pesos per kilogram of muscles (approx. \$13.9 USD), during the season of 2004. Minor landings of the Atlantic species *Nodipecten nodosus* occurred sporadically along the coastal points of Colombia, Venezuela and Brazil. Distribution is patchy and they are not particularly abundant in any one locality. Most of the catch is incidentally taken by shrimp trawlers. No attempts have been made to estimate population size or structure in any area. The special distribution and temporal variation of *Nodipecten* spp are in abundance in México, Venezuela, Colombia and Brazil. The lion's paw scallop is characterized by extreme dynamism. Directed fishery for this species is disproportionally dependent on a single or a few, often well spaced, year-classes. The rapid growth of L. Paw scallop, on the other hand, has been more persistent particularly in the northern aspect of the bank.

GROWTH IN RECOVERING BEDS OF TASMANIAN SCALLOPS (*PECTEN FUMATUS*). Malcolm Haddon, Jayson Semmens and Julian Harrington. Marine Research Laboratory, Tasmanian Aquaculture and Fisheries Laboratory, University of Tasmania, Private Bag 49, Hobart, Tasmania 7001, Australia.

Stratified random dredge surveys demonstrated that Tasmanian scallop beds and the fishery reliant on them collapsed over the 1999/2000 period. The series of annual surveys (at least) that followed this event provided the opportunity to detect and follow the growth of particular cohorts in scallop beds as they re-established themselves. Beds of different densities established themselves in different regions and their growth characteristics were different. The only scallop beds surveyed in the State of Tasmania's waters were all relatively dense. Conversely, the only scallop beds found in Australia's Commonwealth waters near Tasmania were of relatively low density, at least up until 2004. It was only the discovery of a very dense scallop bed in Commonwealth waters in 2004 that permitted a more thorough comparison of growth rates across geographical areas and density. The stock collapse meant that new cohorts could be identified and their growth followed through time. Modal analysis was used to characterize the size distributions of scallops sampled off the beds. Comparison of the relative growth rates of scallops from different areas and densities indicated that density of scallops influenced growth rates, especially after reaching between 70 and 80 mm shell

length. Such variations in growth rate have significant implications for stock recovery times and thereby any fishery, based on the stocks. The minimum time to reach the legal minimum length provides an indication of the minimum number of alternative scallops beds that need to be available to any rotational or paddock harvesting regime.

COMPARISON OF DREDGED BENTHIC FAUNA FROM AREAS OF DIFFERENT FISHING INTENSITY—EXAMINING THE EFFECTS OF FISHING DISTURBANCE. Julian Harrington, Jayson Semmens and Malcolm Haddon. Marine Research Laboratories, Tasmanian Aquaculture and Fisheries Institute, University of Tasmania, Private Bag 49, Hobart, Tasmania 7001, Australia.

Vessel monitoring system (VMS) data from the 2003 Tasmanian and Commonwealth Central Bass Strait commercial scallop (*Pecten fumatus*) fisheries, Australia, was used to define 500 m × 500 m areas that were impacted by different levels of dredge fishing. Dredge samples were subsequently collected from heavy, moderate and low fished areas of the Tasmanian fishery; and heavy, moderate, low, not-fished and pre-fishery (samples that were collected pre-commercial fishing but overlapped areas that would be fished during 2003) areas of the Commonwealth fishery and the data compared to test for differences in the benthic communities found in areas impacted by different levels of fishing intensity. Results from the Tasmanian fishery found significant differences in the benthic communities collected from heavy fished areas and moderate/low fished areas, while in the Commonwealth fishery, benthic communities from areas that were fished (heavy, moderate and low fished blocks) were significantly different from those from not fished and pre-fished areas. These results do not seem to be a consequence of fishing disturbance itself, but are more likely caused by pre-existing habitat and/or benthic community differences, which occur over the same spatial scale as the defined fishing intensity areas.

EFFECTS OF SEA STAR AND CRAB PREDATORS ON SEA SCALLOP (*PLACOPECTEN MAGELLANICUS*) RECRUITMENT IN THE MID-ATLANTIC BIGHT (USA). Deborah R. Hart. NOAA/Northeast Fisheries Science Center, 166 Water Street, Woods Hole, MA 02543, USA

This study investigated the spatial distribution and potential mortality on juvenile sea scallops (*Placopecten magellanicus*) in the Mid-Atlantic Bight imposed by three potential predator groups: the sand star *Astropecten americanus*, the common sea stars *Asterias vulgaris* and *A. forbesi*, and by the crabs *Cancer irroratus* and *C. borealis*. Both asteroid groups appear to reduce sea scallop recruitment, with significantly lower recruitment in areas where the sea stars were in high abundance. However, no significant effect of *Cancer* crabs on scallop recruitment was detected. *A.*

americanus was most common in deep water (>75 m), *Asterias* in shallow water (27–40 m), while *P. magellanicus* was most common at intermediate depths (50–70 m). Very high densities of *A. americanus*, no sea scallop recruitment, and low *Asterias* densities were observed in all stations with depth greater than 85 m, and in many stations between 65–85 m. *A. americanus* may be an unusual type of “keystone” predator that is capable of excluding sea scallops and perhaps other prey species by direct consumption of newly settled spat, and may be excluding *Asterias* by competition and/or predation on its juveniles.

ROTATIONAL MANAGEMENT OF THE UNITED STATES ATLANTIC SEA SCALLOP FISHERY. Deborah R. Hart. NOAA/Northeast Fisheries Science Center, 166 Water Street, Woods Hole, MA 02543 USA.

A general theory of rotational fishing is developed and applied to the United States Atlantic sea scallop (*Placopecten magellanicus*) fishery. Rotation generally increases biomass-per-recruit, and in the case of sea scallops, slightly increases yield-per-recruit for fishing mortalities near F_{MAX} . More substantial increases in biomass- and yield-per-recruit occur at higher fishing mortality rates. Thus, rotational management can help alleviate the effects of over-fishing, and can be considered as contributing to a precautionary approach to fishery management. Rotation increases the yield from cohorts that become of exploitable size at about the time that their area is closed, but this is in large part cancelled by the loss of yield from cohorts that reach exploitable size at about the time the area is opened. This suggests that an adaptive rotation strategy that closes an area to protect a large year-class can give greater improvements in yield than regular rotation. Simulations indicate that adaptive rotation can give further improvements in yield with less area closed at any given time. However, rotation, and especially adaptive rotation, can increase the variability of yields. Rotational management and permanent closures can cause difficulties with conventional metrics of fishing mortality that are based on the assumption that mortality is spatially uniform. Averaging over time rather than space can give a more appropriate measure of fishing mortality when this quantity varies spatio-temporally.

STOCK EVALUATION OF KING SCALLOP (*PECTEN MAXIMUS*) FISHERY OFF THE SOUTHEAST COAST OF IRELAND USING HIGH RESOLUTION ACOUSTIC. Antonio Hervas,¹ Gerry Sutton,² John Hickey³ and Oliver Tully.³ ¹Trinity College Dublin; ²Coastal and Marine Resource Centre, University College Cork; ³Board Iascaigh Mhara, The Sea Irish Fisheries Board, Ireland.

The king scallop fishery off the south east coast of Ireland is by far the most important scallop fishery and one of the major shell-fish fisheries in Ireland. The South East coast of Ireland has had an active scallop fishery since the 1970s, however it was not particu-

Figure 1. Image showing catch rate for four of the stations carried out during the 2002 research survey. The two main acoustically distinct sedimentary facies are shown. Dark features represent gravel lag while light represent sand cover. Catches were significantly higher over dark than over light features.

larly well developed until the 1980s when a large number of boats (approximately 10 boats of 20–30 m in length) entered the fishery. During the 1990s fishing effort increased significantly from 10 vessels and approximately 100 dredges to more than 20 vessels and over 500 dredges. As a consequence of this the fishery experienced a decline in catch rates. This decline in catches was experienced in the traditionally fished scallops beds and as a result boats now have to go to offshore waters to look for larger catches. Due to this worrying development, the South East Shellfish Association saw a need for developing stock assessment procedures for the stock in their region to provide scientific data, which heretofore the fishery was lacking. In summer 2001 a collaborative research project began between BIM (Board Iascaigh Mhara—The Irish Sea Fisheries Board) and the South East Shellfish Association for the development of stock assessment procedures of the scallop fishery off the southeast of Ireland with the aim of developing a system for man-

agement. Annual research surveys have been carried out in the area of study to map the distribution and abundance of the prerecruits and recruits scallops. Type of sediment exerts a strong influence on the distribution of scallop and the understanding of how sediment type affects the distribution of scallops has been a key issue for the annual research surveys carried out since 2002. The objective of the study is to examine the distribution of the scallop stock in comparison to sea floor sediment distribution with particular attention to the effects of small-scale sediment variability on the abundance and distribution of the stock. MBES sonar data were collected by the project team using the RV Celtic Voyager of the National Marine Institute equipped with a Simrad EM 1002. Coherent overlapping (20% to 30%) swaths of sonar coverage were generated within discrete blocks whose size and location were prioritized in order to coincide with areas traditionally fished by the scallop fleet. All MBES data were managed and post-processed using CARIS hydrographic information processing system (HIPS, CARIS, 2003). Stock assessment research surveys were conducted on board a commercial vessel. Twelve scallop dredges (six on port and six on starboard) with ring size 65 mm and tooth spacing of 44 mm were used on the surveys in order to map the distribution of commercial and undersize scallops. Dredges were towed for approximately 30 min at 2.5–3.0 knots. Research cruises have been designed based on the multibeam acoustic map. Transects were plotted in order to find variability in catch rate within small scale areas where the two dominant facies occur. The relationship between sediment type and scallops density will be investigated for different size groups and scallop beds. GIS is an essential element of study, and ArcView (V3.3) has been used to provide a common platform in which all spatial data are integrated and where analytical operations are undertaken. Tasks range from initial operational planning for survey coverage through to data integration, analysis, presentation and map production. All data are projected from WGS 84 geographic co-ordinates to a common reference frame in UTM. Tabulated point data (sediment samples, photographic locations, scallop sample tow locations) are imported via

Figure 2. Log commercial scallops (left) and log juveniles scallops (right) against backscatter for 2002 research cruise. Commercial and juveniles catch rate and sediment type relationship is explained by 69%.

SQL, whereas MBES data products are imported directly. Sediment type was found to exert a strong influence on scallop catch rate (Fig. 1). Preliminary results show high relationship between the acoustic backscatter strength and density of scallops (Fig. 2).

Further analysis will investigate the relationship between sediment type and density of scallop for different size groups and different areas in order to account for those factors that can have an effect on the small-scale variability of the stock. Preliminary results show that sediments exert a strong influence on the distribution of scallops. Multibeam backscatter data can be used to produce high-resolution maps of seafloor sediment variability. The high correlation between survey catch rates and backscatter values can serve for management decisions. Information of scallop density for each of the dominant facies can be used to distribute fishing effort. The better selection of areas to fish for scallops would decrease the adverse impacts of dredging and would decrease the cost of the fishing operation. The strong links between sediment type and scallop abundance would permit to develop more precise ways to estimate scallop stock that would account for sediment-stock relationship.

A REVIEW OF SCOTTISH SCALLOP ASSESSMENTS 1989 TO 2004. Trevor R.W. Howell, FRS Marine Laboratory, PO Box 101, 375 Victoria Road, Aberdeen, Scotland, AB11 9DB.

The scallop (*Pecten maximus* L.) was first fished for commercially in Scotland during the 1930s and has developed into a fishery with annual landings now exceeding 10,000 tons worth £18 million. The fishery is managed by the Scottish Executive Environment and Rural Affairs Department (SEERAD). In order to manage the fishery effectively SEERAD rely on scientific advice on the state of the main scallop stocks in Scottish waters provided by Fisheries Research Services Marine Laboratory Aberdeen (FRS). Assessments of the stocks are presently carried out by FRS biennially using methods established during an internal scallop workshop held in 1990 (Cook et al. 1990) and refined during subsequent internal workshops held 1991 (Bailey et al. 1991), 1994 (Anon. 1995), 1997 (Bailey et al. 1998), 2001 (Bailey et al. 2001), 2002 (Howell et al. 2003) and most recently in 2004 (work in progress). The two main components of the assessment process are described in the presentation: numerical methods using virtual population analysis (VPA) and fishery independent surveys of the major Scottish fishing grounds. Initially an annual VPA was used to take advantage of an extending series of official landings and effort data, combined with age and length data sampled from commercial catches. In view of the pronounced seasonality of the scallop fishery the internal workshop switched to quarterly VPA in 1991. Annual fishery independent surveys to complement the VPA and to provide the most up to date information on the scallop stocks were introduced on the West coast of Scotland in 1992. By 1995 further annual surveys covering the East coast and Shetland fishing grounds were included to give comprehensive coverage of

the major Scottish scallop stocks. Biological work in support of the assessments is also discussed. The results of recent assessments are presented along with a description of current legislation in relation to scallop fishing in Scotland. In the final part of the presentation recent developments with potential for future Scottish scallop assessments are discussed. This includes a description of an effort-mapping scheme that uses scallop fishing vessel GPS data, the GSM (mobile phone) network and the Internet to provide real time location and haul data. These are used in conjunction with catch and landings data from tallybooks filled in by the vessels' skipper. Combined, these data give detailed accurate spatially ordered information on CPUE. The system, used successfully in studies on the Scottish *Nephrops* fishery is presently undergoing trials with Scottish scallop vessels.

FOOD SOURCES OF SCALLOPS AND OTHER BENTHIC ORGANISMS—ARE ENRICHED CARBON RATIOS IN BENTHIC CONSUMERS CAUSED BY BENTHIC PRIMARY PRODUCERS? John H. Himmelman and Marc-Olivier Nadon, Département de Biologie, Université Laval, Quebec City, Quebec, Canada.

We used stable isotope analysis to investigate the sources of primary productivity (phytoplankton, kelp and benthic microalgae) and the trophic structure of benthic food webs in the region of the Mingan Islands, northern Gulf of St. Lawrence. Benthic consumers were rich in ^{13}C , seemingly indicating a strong dependence on ^{13}C -rich benthic primary producers (kelp and benthic microalgae) as opposed to ^{13}C -depleted phytoplankton as a food source. However, suspension feeders, the scallop *Chlamys islandica*, taken along a depth gradient and individuals suspended in cages away from shore were even more enriched in ^{13}C than individuals on the bottom near shore, suggesting that inputs from near shore benthic primary producers are not the cause of the enriched carbon ratio in these organisms. A review of previously reported isotopic ratios from arctic and temperate regions showed that deposit and suspension feeders are almost always enriched compared to the ^{13}C -depleted ratio of phytoplankton, regardless of their distance from ^{13}C -rich primary producers (measured as depth). Thus, our data for the Gulf of St. Lawrence are consistent with those reported elsewhere. Factors other than the feeding on ^{13}C -rich benthic primary producers must explain the carbon ratios in benthic consumers (e.g., possibly strong selective feeding on enriched particles). Finally, three distinct trophic groups characterize the benthic communities in the northern Gulf of St. Lawrence, primary producers, primary consumers (herbivores) and predators, with only a few organisms falling outside of these groups. The sea star *Crossaster papposus* and the sculpin *Myoxocephalus scorpius*, known to be top level predators, were positioned at a slightly higher level than other predators. The relatively small number of organisms located at intermediate trophic levels indicates a low level of omnivory in this system, and this contrasts with previous studies of benthic systems.

FORCE RECORDINGS DURING ESCAPE RESPONSES OF THE GIANT SCALLOP, *PLACOPECTEN MAGELLANICUS*.

Xavier Janssoone,¹ Pierre Gildas Fleury,² Madeleine Nadeau,³ Bruno Myrand,³ Hernan Perez Cortez¹ and Helga Guderley.¹

¹Université Laval, Département de biologie, Québec, P.Q. Canada G1K 7P4; ²Institut Français de Recherche et d'Exploitation de la MER, Laboratoire Environnement Ressources, 56470 La Trinité-sur-mer, France; ³Ministère de l'Agriculture, des Pêcheries et de l'Alimentation, Station technologique maricole des Îles-de-la-Madeleine, Cap aux Meules, P.Q. Canada, G4T 1C6

Giant scallops, *Placopecten magellanicus*, respond to the presence of starfish predators with an escape response consisting of a series of rapid valve adductions that allow the scallop to jump or swim away from the predator. To evaluate the co-ordination of the activity of the tonic and phasic muscles during such escape responses, we recorded their force production by attaching a force gauge to the shell of intact scallop and then stimulating the scallop with a starfish. These recordings showed series of phasic contractions (claps) separated by prolonged tonic contractions. Numerous characteristics could be quantified from these recordings including the maximal force, mean force during the first minute, force, frequency and number of claps per series, as well as the force and duration of tonic contractions. The number of claps per series declined and the duration of the tonic contractions increased as the escape response continued. For most scallops, the rapid phasic and sustained tonic contractions reached a similar force that changed little during the escape responses. The alternation between phasic and tonic contractions suggests that periods of tonic contraction allow the phasic muscle to recuperate and facilitate subsequent phasic contractions. Principal component analysis (PCA) confirmed the co-ordination between the phasic and tonic contractions, because various characteristics of these types of contractions were closely associated.

Figure 1. Force production by *Placopecten magellanicus* during stimulation with *Asterias vulgaris*. Note alternation between phasic and tonic contractions and decreases in clapping frequency as the measurement progresses.

This method combines the advantages of the simplicity of force recordings and the biological relevance of stimulation of the scallops with their predator. Patterns of force production during escape responses by individual scallops were highly reproducible, suggesting these measurements have considerable potential for tracking changes in the physiological status of giant scallops. Examination of changes in escape responses, after air exposure and after handling during mechanical sorting of scallops, is in progress.

EVALUATION OF THE EFFECTIVENESS OF SPATIAL FISHING CLOSURES IN THE QUEENSLAND SAUCER SCALLOP (*AMUSIUM JAPONICUM BALLOTI*) FISHERY 1997 TO 2004. Eddie Jebreen, Sandra O'Sullivan, Michael O'Neill and George Leigh. Department of Primary Industries and Fisheries, PO Box 76, Deception Bay, Qld Australia 4508.

In 1996 the catch rate and total catch of scallops (*Amusium japonicum balloti*) from the Queensland scallop fishery declined markedly. In response to the decline, the Department of Primary Industries and Fisheries (DPI&F) implemented 3 permanent spatial fishing closures, referred to as scallop replenishment areas (SRA's), to reduce fishing mortality on spawning stocks and enhance recruitment to the fishery. In 2001 the area covered by the SRA's was doubled and a rotational harvest strategy developed to permit fishers access to the high densities of scallops within the SRAs. In conjunction with the creation of the closures in 1997, DPI&F established a series of annual fishery independent surveys to monitor the effectiveness of this management strategy. The performance of the SRAs and the rotational harvest strategy was assessed by investigating the relationship between scallop abundance (i.e., standardized catch rate), and closure duration (weeks closed prior to survey) using generalized linear models. The results show a significant relationship between scallop abundance and closure duration, with abundance continuing to increase for closed periods up to 4 years. This result suggests the potential of these areas to act as a source of egg production increases with duration for periods of up to 4 years.

MANAGING SCALLOP SUSTAINABILITY AND YIELD THROUGH SPATIAL AND TEMPORAL CLOSURES IN THE SHARK BAY AND ABROLHOS ISLANDS AND MID-WEST SCALLOP FISHERIES. M. L. Joll,¹ M. I. Kangas² and E. C. Sporer.²

¹Department of Fisheries WA, Commercial Programs, Locked Bag 39, Cloisters Square Post Office, Perth WA 6850, Australia; ²Department of Fisheries WA Western Australian Marine Research Laboratories, PO Box 20, North Beach, WA 6920, Australia.

The Shark Bay scallop and Abrolhos Islands and Mid-West trawl fisheries are the major scallop fisheries in Western Australia (WA). The two areas have had a combined value of \$5–\$20 million per annum during the last 5 years. They are important fisheries

for regional WA providing employment for fishers and associated processing and support industries.

In recent years, with relatively low predicted catch and with high variability that is inherent in scallop fisheries, industry, researchers and management have looked at harvesting options and management strategies to optimize the value of scallop meat harvested in the Shark Bay and the Abrolhos Islands and Mid-West scallop fisheries. These new approaches are currently experimental. This study describes the various ways that spatial and temporal closures and fleet manipulation is used to manage the sustainability of and to optimize the yield of the saucer scallop *Amusium balloti* and how different approaches are taken in different fisheries because of the life-history traits of each area. We also discuss how spatial and temporal closures can be used to address resource-sharing issues between prawn and scallop trawl sectors, other commercial fishers and recreational fisher interests. The introduction of VMS, the relatively small number of operators and good communication links and working relationships between license holders, skippers, research and management provides for opportunities for experimental approaches in the WA scallop fisheries.

CATCH PREDICTIONS AND ENVIRONMENTAL INFLUENCES ON RECRUITMENT OF THE SAUCER SCALLOP *AMUSIUM BALLOTI* AT THREE LOCATIONS OFF WESTERN AUSTRALIA. M. I. Kangas, N. Caputi and E. C. Sporer. Department of Fisheries (Western Australia), Western Australian Marine Research Laboratories, PO Box 20, North Beach, WA 6920 Australia.

The saucer scallop (*Amusium balloti*) fisheries in Western Australia (WA) has shown large variations in annual catch reflecting variations in annual recruitment for a fishery and between scallop fisheries that span from Shark Bay to Esperance in southern WA. In recent years, the Shark Bay catch has varied from 1,000 to 22,000 tons, whereas Abrolhos Is. has seen a catch variation of 150 to 6,000 ton. This study describes the variation in scallop recruitment in the Shark Bay, Abrolhos Is. and Esperance scallop fisheries and explores the environmental influences on recruitment strength. The strength of recruitment is significantly negatively correlated with the major oceanographic process off the West Australian coastline, the Leeuwin Current, during the spawning season. Because the timing of the spawning season for scallop stocks in various parts of WA is different, the impacts can be variable. The possible modes of action of the current include the flushing of larvae away from suitable grounds and/or reduced spawning stimulus (also may be temperature dependent). Other possible factors affecting recruitment such as the spawning stock and other environmental variables, such as wind strength and water temperature are also examined. A good correlation has been observed from pre-season survey abundances and catches providing a forecasting capability for the main two scallop regions in WA, Shark Bay and the Abrolhos Is. This allows researchers, managers and industry to

determine the most appropriate management (e.g., starting date and duration) and marketing strategies for the season.

RELATIONSHIP BETWEEN REPAIRED SHELL DAMAGE AND FISHING DISTURBANCE IN THE PATAGONIAN SCALLOP *ZYGOCILLAMYS PATAGONICA*. Betina Lomovasky,¹ Mario Lasta,² Silvana Campodónico² and Oscar Iribarne.¹ ¹Laboratorio de Ecología, Facultad de Ciencias Exactas y Naturales, Universidad Nacional de Mar del Plata, Mar del Plata, Argentina; ²INIDEP, Mar del Plata, Argentina.

Shell damage and abnormal calcifications are a common phenomenon in bivalve molluscs and can result from a series of interactions or disturbances that often lead to different, distinctive marks. For example, burrowing activities cause damage and chipping of the shell edge (#4, 15). Attack by crabs increases the number of scars in the shell (#16, 10), birds break the posterior margins of the valve (#9, 1, 15) or fragment the shells (#2, 3) leaving recognizable marks. Moreover, disturbances such as commercial dredging, increase the incidence of scars in the shells of *Artica islandica* (#21), *Glycymeris glycymeris* (#17), *Ensis arcuatus* (#19) and *E. siliqua* (#6,7). If properly evaluated, all these marks can be useful to understand the relative importance of different disturbance sources in different locations. *Zygocillamys patagonica* is distributed around southern South America reaching 42°S in the Pacific to Tierra del Fuego (55°S) and 35°50'S in the Atlantic between a depth-range of 40–200 m (#5, 8, 13, 20), being an important economic resource (#12). Grounds in the Pacific occur in relatively shallow waters whereas in the Atlantic they are located along the 100 m isobath (#12). A fishery on this species started in Argentinean waters in 1996 (#12) and mainly involves four factory trawlers that process the catch on board. The fishing reached 42,969 tons scallops⁻¹ with landings of 6,018 tons meat⁻¹ during 2003 (#14). Given their importance, the identification and description of the microstructure of repaired shell damages in extant populations may be useful to understand the repairing mechanisms and infer ecological processes or possible impact of the fishery on different beds. With this purpose, we identify and describe the microstructure and frequency of repaired shell damage found in different beds and compared it with the local area swept intensity. Samplings of *Z. patagonica* ($n = 2047$) were performed in 4 beds (Uruguay: 36°17'S to 53°49'W; Reclutas: 39°20'S to 56°W and 39°30'S to 55°52'W; Tango B: 42°30'S–59°05'W and Beagle: 55°10'S to 66°05'W) during 2000 and October 2004 (Beagle bed) using a total of 24 trawls. The relative intensity of commercial fishing, prior to the sampling date from 1996 to 2000, was indirectly estimated using the swept area which was calculated by considering total number of tows, speed (km h⁻¹), towing time (minutes) and 68% of the foot rope length (#11). In TangoB bed the swept area was 448 km², in Reclutas all sampled were taken from an exclusion fishing area (EFA) with a 0.3 km² swept area done for scientific purpose. Fishing by the commercial fleet in

Uruguay bed was related to prospecting fishing tows so a negligible disturbance of 12 km² swept area was estimated. No fishing was done in the Beagle bed. The frequency of shell damage was estimated by visual examination of the valves of all specimens. Acetate-peels technique was used to identify internal shell damage (#18). Under reflecting light, acetate peels from the polished shell cuts showed a pattern of alternating broad opaque and narrow translucent growth bands. Repaired shell damages were observed in some individuals in different parts of the valve. In general, during the process of shell repair, sediment particles were trapped in the damaged area between the old and newly accreting shell. The photomicrographs of acetate peels showed alterations in the growth band deposit, and sediment grains into the shell matrix between two growth-bands. A similar pattern of repaired shell damage is described for *Ensis siliqua* (southern Portugal) due to dredging operation (#6). The incorporation of sediment grains into the shell matrix occurs in other bivalves, such as *Arctica islandica* (#21) because of the effect of suction dredging and, to a lesser extent, predator attacks. A similar process of sediment intrusion, but caused by unsuccessful predator attacks, has been described for *Lutraria lutraria*, *L. magna*, *Panopea glycymeris*, *Ensis siliqua* and *Solen vagina* (#4) and *Tagelus plebeius* (#15). The frequency of repaired shell damage in scallops from different beds analyzed in this study showed a higher percentage in TangoB bed (32%) than Uruguay and Reclutas (12%), with the lower value in Beagle bed (9%). The commercial fishery intensity in the 4 beds showed the higher intensity in TangoB, next Reclutas (with only a minor research disturbance in the area) and Uruguay bed (negligible disturbance) with null fishing intensity (no disturbance) in the Beagle bed. The frequency of damaged scallop observed in those beds-areas not targeted by the fishery (Uruguay, EFA in Reclutas and Beagle bed), assuming not anthropogenic disturbance by fishing, could be related to all natural causes of disturbances that produce injury to be repaired (i.e., predation). The difference between the 32% of scallop damaged in Tango B with values on none (or negligible) disturbed beds could be attributed to the fishery impact or disturbance in the bottom. A positive correlation between the incidence of scars in the shells of *Arctica islandica* (#21), *Ensis siliqua* (#6) and *E. arcuatus* (#19) and the intensity of commercially dredged was observed. If we consider that scallops make a major energetic investment in repairing their shells, which is likely to affect their growth rate at the expense of adductor muscles mass, then the fishery may be having some non-lethal effects on the Patagonian scallop populations. Given the importance in some beds, this potential effect needs to be studied.

- MORPHOMETRIC VARIATIONS AND INTERNAL SHELL GROWTH PATTERNS OF THE PATAGONIAN SCALLOP *ZYGOCHELAMYS PATAGONICA* ACROSS THEIR SW ATLANTIC DISTRIBUTION RANGE.** Betina Lomovasky,¹ Mario Lasta,² Macarena Valiñas,¹ Martín Bruschetti,¹ Silvana Campodónico² and Oscar Iribarne.¹ ¹Laboratorio de Ecología, Facultad Ciencias Exactas y Naturales, Universidad Nacional de Mar del Plata, Mar del Plata, Argentina; ²INIDEP, Mar del Plata, Argentina
- Zygochlamys patagonica* is widely represented (depth range between 40–200 m; #6, 9, 13, 20) in the extreme of South America (reaching 42°S in the Pacific to Tierra del Fuego (55°S) and 35°50'S in the Atlantic), being an important economic resource in the Atlantic. In the Pacific, main grounds occur in relatively shallow waters (#1) whereas in the Atlantic they are located along the 100 m (#12). Growth and age of *Z. patagonica* were determined from surface external rings (#18, 7) and chondrophores (#20, 19, 5). However, more precise studies are needed to identify internal growth bands, such as acetate peels technique (#16), to validate the external growth rings avoiding error in estimating individual age. Growth, production and physiological activity of bivalves can be affected by environmental conditions (e.g., temperature, salinity, substrate, food-availability; #3, 8, 10, 11). However, density-dependence (#21, 8, 9) and biological interactions could also have an important effect. Individuals from different beds along the Atlantic may have different growth pattern, maximum age and morphometric relationships. We evaluate this prediction comparing different beds along a latitudinal gradient in the south-western Atlantic. Samplings of scallop (24 tows; n = 2,047) were performed in 4 beds (Uruguay: 36°17'S to 53°49'W; Reclutas:

39°20'S to 56°W and 39°30'S to 55°52'W; TangoB: 42°30'S to 59°05'W and Beagle: 55°10'S to 66°05'W) between January 2000 and October 2004. We measured shell height (H: umbo-ventral margin), length (L: anterior-posterior axis) and width (W: precision ± 0.1 mm), and total mass without epibionts (TM), shell mass (SM), shell free wet mass (SFWM), gonadal mass (GM), adductor muscle mass (AMM) and epibionts mass (EM; precision ± 0.01 g). Morphometric relationships were determined and log-log transformations were applied when necessary and compared with ANCOVA between beds. Unplanned comparisons (Tukey multiple comparison, TMC) were made when significant differences were found (#22, 17). For growth and age analysis sub-samples were taken ($n = 605$). Growth pattern observation was inferred from internal shell growth bands using acetate peels technique to allow microscopic examination (#16). The size-mass relationship between TM, SM, SFWM, AMM, GM and EM (dependent variables) and H (independent variable) was exponential in each bed and there was a linear relationship between L and W with H ($P < 0.01$) for all beds. However, the slope of L-H relationship differed between beds ($P < 0.001$); Uruguay and Reclutas beds were similar and differed of TangoB and Beagle (TMC, $P < 0.05$). Similar results were observed for W-H and $\log(\text{TM})$ - $\log(\text{H})$ relationships. For $\log(\text{SM})$ and $\log(\text{SFWM})$ with $\log(\text{H})$, the slopes differed between beds ($P < 0.001$). All beds differed each other (TMC, $P < 0.05$). There were no differences for the relationship $\log(\text{EM})$ - $\log(\text{H})$ between beds (ANCOVA: $F = 0.71$; $P = 0.5446$). There was an increase in all variables following a latitudinal gradient N to S. Under reflecting light, acetate-peels from the polished shell cuts showed a pattern of alternating broad opaque and narrow translucent growth bands. Growth pattern and maximum age differ between beds. There was a similar pattern of internal bands between Uruguay and Reclutas (maximum age of 13 and 14 years old respectively). Internal growth bands in the umbo were clearly observed. It was possible to follow the translucent growth bands all the way along a cross section of the shell to the point where they cross the outer shell layer to form a ring on the exterior shell surface. The 2–3 first bands, difficult to observe along the shell section, showed a different pattern from other growths bands. Each growth break (i.e., an external ring) of the recent bands was formed with a group of internal growth bands (cluster shape). Thus, these clusters were formed by a growth rate slowed down during some periods within a year but not by a total interruption in growth. At the last portion of the valve (recent bands), the internal growth bands were closer to the shell edge and were proximate each other (individuals >50 mm H), clearly visible in acetate peels but difficult to identify on the exterior shell surface. Internal growth bands in the umbo and along the cross section were similar in TangoB but it was difficult to observe the point where the translucent bands cross the outer shell layer to form an exterior ring. The cluster shapes of these exits were less pronounced. Maximum age was 20 years old. Beagle bed showed a higher shell thickness along the cross shell section, as was refluxed in a higher shell mass (see

earlier), where was possible to see all the internal growth bands. The point where the translucent growth bands form an exterior ring did not have a cluster shape; they were a simple translucent growth band. Thus, a total interruption of growth seems to be the cause of this external ring. Maximum age was 21 years old. Acetate-peels technique allows us to obtain new information on the maximum age across the latitudinal gradient. The presence of translucent growth bands indicate periods of very slow or even halted shell growth, possibly caused by low metabolic rates related to a lack of food (#4, 3, 11) or by a diversion of metabolic products into gamete production (#2, 15, 14). The influence of 1°C to 2°C annual variation in temperature in the studied areas seems to be negligible to explain variations detected by our study. However, other factors such as density-dependence, different biological interactions and food availability, could explain the differences found between populations inhabiting different latitudes.

THE EFFECT OF PHOTOPERIOD ON THE CONDITIONING OF THE BLACK SCALLOP, *CHLAMYS VARIA*.

1—GONADAL DEVELOPMENT. A. Louro,¹ J. P. De la Roche,¹ J. L. Sánchez,² A. Silva,² P. Martínez,² M. L. Pérez-Parallé,² I. Martínez² and G. Román.¹

¹Instituto Español de Oceanografía, Centro Oceanográfico de A Coruña, PO Box 130, 15080 A Coruña, Spain; ²Universidad de Santiago de Compostela, Instituto de Acuicultura, Departamento de Bioquímica y Biología molecular, 15782 Santiago de Compostela, Spain.

Despite different studies having been carried out on the subject, the effect of photoperiod on gametogenesis in bivalves is still not clear. Reproduction was stimulated in *Placopecten magellanicus* (Couturier & Aiken 1989) and *Pecten maximus* (Devauchelle & Mignant 1991, Paulet & Boucher 1991) by increasing the length of photoperiod. Saout et al (1999) found that a simultaneous increase in temperature and length of photoperiod enhanced gonad growth in *P. maximus* when food was not limiting, although they did not determine which of the two factors was the most important. Silva et al. (2002) described acceleration of gonad development of *Ruditapes decussata* in winter, when spring photoperiod conditions were maintained. In this study, comparison is made of gonad development in black scallops subjected to two different day length regimes. Scallops (30 months old) grown by suspended raft culture on the Galician coast were collected in October and November during the gonad-resting period. (De la Roche et al. 2005). Two experiments were carried out; in experiment 1, carried out between November 8, 2002 and 22 February 2003, 264 scallops were used; the mean temperature was $17.4 \pm 1.5^\circ\text{C}$. In experiment 2, carried out between 10 October 2003 and 5 January 2004, 280 scallops were used; the mean temperature was $15.0 \pm 1.1^\circ\text{C}$. A mixture of *Skeletonema costatum*, *Isochrysis aff. galbana*, *Pavlova lutheri*

and *Rhodomonas salina* cells (mean 2.5×10^{11} cells day⁻¹) was added to the tanks (180 × 50 × 30 cm) in which the scallops were maintained. In each experiment, the scallops were divided in two groups of equal number, and subjected to a day length of 16 h (LP) or a day length of 8 h (SP). A total of 15 individuals were dissected to determine initial conditions. Samples of 15 scallops were periodically removed from each experimental tank, the different organs dissected and the dry weight recorded. A predictive regression between height and dry weight of the organs was calculated and the mean values for a standard scallop of 50-mm height was estimated. There were clear differences in gonad development in scallops maintained under the different day-length regimes. In experiment 1, under LP conditions, gonads showed growth at 15 days, and maximum values (mean 0.23 g) were reached after 60 days, followed by spawning. Scallops maintained in SP conditions showed slower gonad development, the maximum values (mean 0.16 g) were reached after 82 days, followed by spawning. In experiment 2, very fast gonad growth was recorded under LP conditions, reaching a peak value (0.25 g) followed by spawning, after 40 days. The subsequent decrease in gonad size was followed by a rapid recovery and a new peak value (mean 0.35 g) was recorded 1 month later and was followed by a second spawning. Scallops maintained under SP conditions did not develop gonads between October and December. In general, the digestive gland showed a slight increase in weight parallel to that of the gonad, probably because as gonad grows it envelops the gland, and the weight of the digestive gland included a small amount of gonad. The weight of muscle tended to decrease throughout the conditioning period. Variations in the dry weight of the remaining tissues were not observed. Under conditions of spring day length (LP), at moderate temperatures (experiment 2, $15.0 \pm 1.1^\circ\text{C}$) and

Figure 1. Changes in gonad dry weight in wild scallops and in scallops held under two photoperiods and temperatures. Values are standardized for a shell height of 50 mm.

with abundant food, in approximately 3 months (October to December)

The scallops underwent the complete bimodal breeding cycle previously recorded under natural conditions at sea (February to June, De la Roche et al. 2005), whereas under conditions of winter day length (SP) gonad growth failed to start. At higher temperatures (experiment 1, $17.4 \pm 1.5^\circ\text{C}$) gonad growth took place under both conditions of day length. In the latter case, the gonad development under LP conditions was slower than in scallops maintained at 15°C . However, at 17.4°C gonad growth took place even in scallops maintained under SP conditions.

DETERMINING THE OPTIMAL SCALLOP SPAT LENGTH AND TRANSPORT CONDITIONS FOR *PECTEN NOVAEZELANDIAE* DURING THE SEEDING ENHANCEMENT PROGRAM IN NELSON, NEW ZEALAND. Rebecca L. Lyon¹ and Islay D. Marsden.² ¹Ministry of Fisheries, Aquaculture Team, Private Bag 14, Nelson, New Zealand; ²School of Biological Sciences, University of Canterbury, Private Bag 4800, Christchurch, New Zealand.

Scallop meat weight landings in the last 5 years peaked at 716 tons in the 2001/2002 season and was worth an estimated \$26 million dollars. The success of the scallop industry relies heavily on a spat enhancement programme run by the Challenger Scallop Enhancement Company Limited. Mesh spat collectors are set during November or December and harvested around March (primary spat). Fall off from the primary spat collectors results in high densities of juvenile scallops on the seafloor, which are harvested as secondary spat. The aim of this research is to determine which length scallop spat was the most robust and therefore most likely to survive the harvesting and relocation processes. Behavioral experiments were conducted on primary spat from 9 different length groups (8–10 mm, 11–12 mm, 13–15 mm, 16–17 mm, 18–20 mm, 21–22 mm, 23–25 mm, 26–27 mm, 28–30 mm) collected during the 2002 primary harvest. When presented with a starfish predator (*Coscinasterias calamaria*), 10 mm spat had a significantly slower reaction time (8.30 ± 0.16 sec) than other length groups and 17 mm length group had the fastest reaction time (2.55 ± 0.32 sec). Small spat had significantly fewer adductions in their first swimming

bout than large spat (12 mm = 8.44 ± 0.61 , 27 mm = 10.90 ± 0.49). Also, small spat exhibited fewer overall adductions than large spat, (10 mm = 2.24 ± 1.58 , 27 mm = 40.52 ± 1.20). Aerial exposure experiments conducted on 3 length groups (20–35 mm, 36–50 mm, 51–65 mm) indicated that scallops could survive up to 8 hours transport at temperatures $<20^\circ\text{C}$. When scallops were acclimated to 18°C , mortality was approximately 15%. However, over 2 hours exposure at a temperature of 30°C resulted in 60% to 100% mortality. This study suggests that scallop spat >20 mm from the primary harvest are the most robust. The secondary harvest should target larger juvenile scallops (>27 mm) when transporting long distances (>8 hours).

TOLERANCE, RESISTANCE AND OPTIMUM VALUES OF TEMPERATURE AND SALINITY, IN THE GIANT LION'S PAW SCALLOP (*NODIPECTEN SUBNODOSUS*). Alfonso N. Maeda-Martínez, Teresa Sicard-González, Lucelly M. Roldán-Carrillo and Flavio González-Estrada. Centro de Investigaciones Biológicas del Noroeste (CIBNOR), Mar Bermejo 195, Col. Playa Palo de Santa Rita, La Paz, B.C.S. 23090, Mexico.

Lower and upper tolerance and resistance and optimum values for growth under different temperature and salinity ranges were studied in juveniles of the giant lion's paw scallop *Nodipecten subnodosus*. Tolerances were measured with the median lethal dose method (LD_{50} –96 h), exposing specimens acclimated initially at 15, 18, 22, 26, or 30°C and 37 psu, to 13 temperatures (1, 3, 5, 10, 15, 26, 28, 30, 31, 32, 33, 34, or 35°C). Halotolerance was determined by subjecting acclimated scallops at 22°C and 37 psu (control conditions) to 9 salinities (15, 20, 25, 30, 37, 42, 47, 50, or 60 psu). Resistance to both variables were studied using a gradual change, decreasing or increasing the temperature $1^\circ\text{C}/\text{day}$ or salinity 3 psu every 3 days from the acclimation temperatures and salinities, until mortality of the test specimens occurred. Optimum values were defined by measuring the scope for growth and by somatic shell and biomass growth determinations at different temperatures (15, 18, 22, 26 and 30°C) and salinities (25, 30, 37, 43, and 47 psu). Results showed that the lower and upper temperature tolerance at 96 h varied from 5.1°C to 12.5°C and 27.8°C to 32.9°C at 15°C and 30°C acclimation, respectively. Salt tolerance varied from 24.2 to 53.8 psu. The lower temperature resistance was not achieved at the lowest temperature tested (3°C) and the upper resistance value was 32°C , independent of the acclimation temperature. Salt resistance experiments showed no mortality in the 22 to 52 psu range, but abrupt mortality occurred with exposure beyond these values. Scope for growth and somatic growth experiments indicated that the optimum temperature and salinity were 22°C and 37 psu. The application of these results to hatchery operations and site selection for growout of giant lion's paw scallop is discussed.

THE EFFECT OF PHOTOPERIOD ON THE CONDITIONING OF THE BLACK SCALLOP, *CHLAMYS VARIA* II—HISTOLOGICAL STUDY. I. Martínez,¹ A. J. Pazos,¹ A. Louro,² J. P. de la Roche,² G. Román,² M. Abad¹ and J. L. Sanchez.¹ ¹Instituto de Acuicultura, Departamento de Bioquímica y Biología Molecular, Universidad de Santiago de Compostela, 15782 Santiago de Compostela, Spain; ²Instituto Español de Oceanografía, Centro Oceanográfico de A Coruña, PO Box 130, 15080 A Coruña, Spain.

The aim of this study is to achieve some progress in the optimization of the conditioning of the black scallop, *Chlamys varia* through suitable manipulation of photoperiod. Several authors have reported that daylight has an important influence on the gametogenesis in marine organism (Pearse et al. 1986, Devauchelle & Mingant 1991, Paulet & Boucher 1991, Saout et al. 1999, Chavez-Villalba et al. 2002). However, results of previous studies on the influence of photoperiod on gametogenic development are often contradictory (Devauchelle & Mingant 1991), and therefore it is not usually taken into account when conditioning procedures are developed (Utting & Millican 1997). We tested black scallops at two different stages of gametogenesis because we assume that the response will differ according to the initial reproductive stage of the progenitors. Two conditioning experiments were carried out (experiment 1: November to February, experiment 2: March to April). Adult scallops grown by raft culture in Galicia, were held in tanks (180 × 50 × 30 cm) in seawater for the conditioning. The mean temperature was $17.4 \pm 1.5^\circ\text{C}$ in experiment 1 and $15.0 \pm 1.1^\circ\text{C}$ in the experiment 2. Scallops were fed a mixed diet of *Skeletonema costatum*, *Isochrysis aff. galbana*, *Pavlova lutheri* and *Rhodomonas salina* (2.5×10^{11} cells · day⁻¹). In each experiment, two photoperiods were tested; in three tanks scallops were maintained fewer than 8 h light and 16 h dark (winter conditions), whereas in other three tanks were maintained under 16 h light and 8 h dark (spring conditions). Every 2 weeks 15 scallops were sampled from each experimental tank and the gonad dissected out. Gonad tissue was fixed in Bouin (5 h) and the tissues were dehydrated in series of alcohols, and embedded in wax. Histological sections (3- μ thick) of each gonad were stained by the Wheatley trichrome method (1951). Specimens were examined microscopically for evidence of gametogenesis. Experiment 1: the scallops maintained under the 16 h light regime showed signs of gametogenesis development after only 15 days of conditioning, whereas scallops maintained under the 8 h light regime remained in resting state after 30 days of conditioning and gonad development was not observed until after 45 days of conditioning, by which time the group of scallops under the 16 h light regime had already spawned. Experiment 2: In scallops subjected to the 8 h light regime there was a certain degree of regression, whereas scallops subjected to the 16 h light regime achieved spontaneous spawning during the first month of conditioning. These results are consistent with those of Saout et al. (1999) who reported that photoperiod is undoubtedly the most important factor involved in the synchronization of

reproduction on pectinids, whereas temperature and nutrition are more important in terms of the speed of the gametogenesis once the process has been established in the animals.

CALCIUM IS AN ESSENTIAL ION FOR THE SPAWNING AND RESUMPTION OF MEIOSIS OF THE SCALLOP *ARGOPECTEN PURPURATUS*. Gloria Martínez, Miguel Angel Pérez and Livia Mettifofo. Facultad de Ciencias del Mar, Universidad Católica del Norte, Larrondo 1281, Coquimbo, Chile.

For some years our research has focused on understanding the control of spawning in the scallop *Argopecten purpuratus*. We have investigated the dynamics of some monoamines and second messengers during this process. Lately, we have shown an increase of inositol 1-, 4-, 5-trisphosphate (IP₃) associated with spawning (Martínez & Cisterna 2004). This messenger binds to the IP₃ receptor, a Ca²⁺ channel in the reticulum endoplasmic membrane and thereby releases Ca²⁺ into the cytoplasm. This finding led us to think that Ca²⁺ is involved in the spawning process. Because smooth muscle contraction is a Ca²⁺-sensitive process, the IP₃ rise may be a required step for increasing intracellular Ca²⁺, which is necessary for the contraction of gonadal muscular tissue and the expelling of gametes. Whereas meiosis in this species is reinitiated

before female gametes are released to the environment, we postulated that Ca^{2+} could also be necessary for meiosis resumption. The aim of the present work is to investigate “*in vitro*” the need of calcium ion for the release of gametes and for meiosis resumption in *A. purpuratus*. Female portions of ripe *A. purpuratus* gonads were cut into small pieces of 30–50 mg wet weight and washed with filtered seawater. Pieces originating from the same individual were incubated for 90 minutes in separate 2 mL glass vials containing one of the following solutions: Artificial seawater (ASW), ASW without Ca^{2+} (0Ca ASW), ASW plus 10^{-5} M serotonin (5-HT), 0Ca ASW + 5-HT, filtered natural seawater (NSW), NSW + 10^{-5} M 5-HT, NSW + 0.25 µM Ryanodine (Rya), NSW + 0.50 µM Rya, NSW + 50 µM Rya, NSW + 10 mM caffeine and NSW + 20 mM caffeine. After incubation, the liberated oocytes were fixed in Carnoy solution for their later counting under light microscope. Different experiments were run to assay the different treatments but each time, the experimental and control solutions were assayed on tissue coming from the same individuals. All the

experimental treatments were replicated eight times, each with a different scallop. Data obtained were subjected to 1-way analysis of variance followed by a Tukey test in order to compare the differences ($P < 0.05$). Gross transverse sections of about 2 mm thickness were obtained from female gonadal portions and were placed in glass dishes containing 5 mL of some of one of the following solutions: NSW, NSW + 50 mM EGTA, NSW + 10^{-5} M 5-HT, NSW + 50 mM EGTA + 10^{-5} M 5-HT, ASW, 0Ca ASW, 0Ca ASW + 5-HT. After 60 minutes, each tissue sample was rinsed with NSW or ASW and superficial scrapes were obtained with a surgical scalpel and were fixed with Carnoy solution. The total number of oocytes, and the number that showed meiosis resumption (visualized by germinal vesicle breakdown, GVBD) were counted under a microscope to calculate GVBD percent. Percentages, subjected to arc-sin transformation were analyzed by 1-way ANOVA. The release of oocytes from gonadal pieces was inhibited when Ca^{2+} was absent from the incubation solution and the usual stimulatory effect of serotonin was blocked. Ryanodine is an alkaloid known to bind Ca^{2+} channels (ryanodine receptors, RyR) in the sarcoplasmic reticulum (SR) and is involved in the release of this ion from intracellular stores. This alkaloid inhibited the release of oocytes at 50 µM in normal and artificial seawater. Low concentrations (nanomolar range) of Rya render the membrane of SR leaky to Ca^{2+} , whereas higher values (µmolar range) prevent Ca^{2+} release (Williams & Tanna 2004). This result suggests that RyR are involved in the process of oocyte release and that Ca^{2+} for the spawning is moving from SR stores. To confirm this we used caffeine, a methylxanthine known to increase Ca^{2+} conductance by RyR (Zucchi & Ronca-Testoni 1997). The release of oocytes was significantly increased when 10 and 20 mM caffeine were used in the incubation medium. Meiosis resumption was blocked in the absence of calcium ion, effect that was detected either in ASW without Ca^{2+} or in NSW plus the calcium quelator EGTA. Calcium ion must be present in the medium for meiosis resumption and release of oocytes from gonad of *A. purpuratus*.

COMMERCIAL SCALLOP CULTURE TRIALS AT THE PINNACLE CHANNEL AQUACULTURE FISHERIES RESERVE, IN SOUTHERN AUSTRALIA. John A. Mercer,¹ Neil J. Hickman² and Richard J. Gasior.² ¹Fisheries Victoria, Department of Primary Industries, PO Box 114 Queenscliff, Victoria 3225, Australia; ²Primary Industries Research Victoria, Department of Primary Industries, PO Box 114 Queenscliff, Victoria 3225, Australia.

Fisheries Victoria facilitated a scallop growing trial at the new 1,000 ha Pinnacle Channel Aquaculture Fisheries Reserve (PCAFR) in southern Port Phillip Bay, Victoria. The aim of the

trial is to evaluate the Reserves' suitability for scallop culture through a series of commercial trials undertaken by prospective scallop farmers. An industry consortium monitored scallop larvae abundance in the water at the PCAFR for 2 years, in order to determine if it were possible to catch commercial quantities of scallops in "spat-bags." Scallops that were caught at the site were used for a range of growing trials. The trial reported here grew a crop of scallops on two under-water commercial long-lines that were held 10 m below the sea-surface in water that was approximately 20 m deep. The seed scallops collected from spat bags in April 2003 were used to evaluate a range of culture nets and containers. The trials involved PIRVic undertaking a trial using a "standard" culture method and industry conducting a range of trials using various culture systems. These trials were run concurrently on the sub surface long-lines. Primary Industries Research Victoria (PIRVic) was commissioned to measure growth rate and meat condition of scallops grown by a "standard" method that used pearl nets for the early nursery stage and box nets for the final grow-out. PIRVic also assisted industry in assessing other methods that were used, including a variety of oyster containers and shellfish growing nets. When using the "standard" growing method, seed scallops that averaged 22.7 mm in length at the start, grew to 79.1 mm with negligible mortality in 18 months. The scallops grew throughout the whole year with slower rates over the colder winter months. Scallop meat condition was variable and ranged from good to poor. An assessment of commercial production was made after 18 months. Only one of the commercial methods investigated performed as well as the scallops that were grown in pearl and box nets and measured regularly by the "standard" growing method. This method was growing scallops in 4.5 mm pearl nets for 9 months then at a low density in large round lantern nets for the final 9 months. All other treatments tested did not perform as well as the "standard" method. It was concluded that many of the physical attributes of the site make the PCAFR a good location for commercial scallop aquaculture. The establishment of the PCAFR by the Victorian Government provides an opportunity for prospective marine farmers to develop a new shellfish aquaculture industry.

MAKING IT WORK—SCALLOP CULTURE AND MANAGEMENT IN NEW ZEALAND. Russell Mincher, Challenger Scallop Enhancement Ltd., P.O. Box 175, Nelson, New Zealand.

Commercial success in fisheries management seldom has a great deal to do with managing the fish. Fish reproduce, grow and die as they have done without human intervention since time immemorial. The fishery manager is concerned with managing people and their behavior so that the fish can get on with the business of growing to harvest condition. That premise holds true for all exploited fisheries, including scallop fisheries whether they are farmed, ranched, enhanced or truly wild. Managing an enhanced scallop fishery to generate a commercial outcome is a

business. It is the business of using the resources available to the organization to influence the productivity, security and profitability of harvests over the long term. The Challenger Scallop Enhancement Company of New Zealand (Challenger) is in that business. Information needs and scientific inputs required by fishery managers in an enhanced fishery change as the fishery matures. Having settled how best to intervene in the reproductive cycle of the fishery to successfully enhance, the manager's focus shifts to improving harvests, improving operational efficiency and resolving threats to the fishery or program. Russell's address describes some of the challenges previously overcome and others currently faced by Challenger as it manages a commercialised scallop enhancement program. Those challenges include:

- Securing on-going funding for the program
- Managing the interface with recreational and customary scallop fishers
- Improving spat survival rates while reducing the costs of enhancement
- Managing harvester behavior
- Protecting the fishery from conflicts with marine farming proposals

SCALLOP (*PLACOPECTEN MAGELLANICUS*) SEA SAMPLING PROGRAM AS A STOCK STATUS INDICATOR.

Monique Niles and Leslie-Anne Davidson, Aquaculture Division, Department of Fisheries and Oceans, Moncton, New Brunswick, E1C 9B6, Canada.

The sea scallop (*Placopecten magellanicus*) fishing grounds in the southern Gulf of St. Lawrence are divided into four Areas. The scallop fishery is managed by imposing seasons, meat count limits, gear size limits and restrictions and logbook reporting. Over the last 4 years, the landings have hovered above 100 mt of meat, the lowest recorded since 1968 when peak values attained 900 mt. Since implementing logbook reporting in 1999, it has become possible to map fishing positions and effort. In 2001, a sea sampling program was put in place in collaboration with the fishing industry to better understand the status and biology of the scallop beds. As a result, recommendations have been made to fishermen and fisheries managers concerning meat count limits and ring size increases. Meat count regulations have decreased from 52 meats/500 g to 44 meats/500 g in one Area, while the ring size has increased from 3 inches to 3¼ inches in all Areas. Also, it has been demonstrated to fishermen that returning scallops to sea that are smaller than 80 mm will not jeopardize their current landings. By adopting these recommendations, it is thought that over time, fishermen could increase their landings and maximize meat yields by targeting scallops larger than 100 mm. Trends in the meat weights of 90 mm scallops have been evaluated against environmental parameters. The sea sampling program has proven to be an inex-

pensive but useful tool in better understanding the scallop stocks, fishery and biology and in giving science-based advice.

AUSTRALIAN SAUCER SCALLOPS—SEA RANCHING GENETICS. Elizabeth O'Brien,¹ Jason Bartlett,¹ Bryony Dixon¹ and Peter Duncan.² ¹Department of Primary Industries and Fisheries, Profitable Aquaculture Systems, Bribie Island Aquaculture Research Centre, PO Box 2066, Woorim, QLD 4507, Australia; ²Faculty of Science, University of the Sunshine Coast, Maroochydore DC, QLD 4558, Australia

The saucer scallop, *Amusium balloti*, is distributed along the Western and Eastern coast of Australia and supports a fishery in both states. To stabilize the annual catch rates, private companies from both states are investing in sea ranching or reseeded operations. Because of biological constraints on wild harvest of spat, the enhancement operations are reliant on production of seed from hatcheries. The mass release of scallop juveniles is expected to have an immediate effect on stock abundance but it also has the potential to alter the genetic structure of the wild saucer scallop populations. To minimize the environmental impacts of reseeded, genetic resource management is recommended, and both companies are supportive of understanding the genetic structure of the native populations. To facilitate this, the genetic population structure of saucer scallops along the Western and Eastern Australian coastline have been analyzed using eight microsatellite loci and the results will be presented during this presentation. Previous allozyme work compared the Queensland and Western Australian forms of *A. balloti*, and results indicated that they might be classed as different species (Dredge et al. in prep.). We have used 16S and 12S rRNA sequence fragments to verify these findings and present the results here. Finally we will present a suggested genetic management strategy for Australian saucer scallop ranching, based on these findings.

THE EFFECT OF TRANSPORTATION ON THE PHYSIOLOGICAL CONDITION AND FREE AMINO ACIDS COMPOSITION OF *NODIPECTEN SUBNODOSUS* ADDUCTOR MUSCLE. V. M. Ocaño-Iliguera,¹ A. N. Maeda-Martínez,² M. E. Lugo-Sánchez³ and R. Pacheco-Aguilar.³ ¹Universidad de Sonora. Departamento de Ciencias Químico Biológicas. Boulevard Luis Encinas y Rosales. Col. Centro. C.P. 83000; ²Centro de Investigaciones Biológicas del Noroeste, S.C. Mar Bermejo No. 195, Col. Playa Palo de Santa Rita. Apdo. The lion's paw scallop, *Nodipecten subnodosus* (Sowerby, 1835) is the largest pectinid in the Baja California Peninsula, Mexico. This scallop is distributed from Ojo de Liebre lagoon, Baja California Sur México, to Peru. At the present time, some

Figure 1. Device used for shipping of lion's paw scallop *Nodipecten subnodosus*.

aspects on culture, reproductive cycle, growth, gametogenesis, postmortem changes and quality of the adductor muscle has been studied in *Nodipecten subnodosus*. However, reports of the transportation effect on the physiology and free amino acids composition in the adductor muscle is very scarce. Therefore the overall objective of this study is to evaluate the effect of transport on the physiology of this scallop, using the changes in adenylic energetic charge, glycogen content, muscle yield index and free amino acids composition as indicators of stress. Scallops *Nodipecten subnodosus* of 6–7 cm shell height were used in the study. A sample of 2,630 individuals was collected and transported from the Guerrero Negro lagoon to the laboratory at the Universidad Autónoma de Baja California Sur, Mexico. The elapsed time for transportation was 11 h. Features of the original shipping device designed by Maeda-Martínez et al. (2000) for scallop seed was substantially modified and shown in Figure 1. Firstly, the organisms were placed on a wood base (100 cm in diameter) and sponge rubber over which, alternate beds of organisms—sponge rubber—organisms were placed. The sponges were soaked with seawater during the packing. Afterwards, a base of wood was collocated on the top, which served as a lid. A rope was used to secure the sandwich of organisms, which was placed inside a 1m³ cooler

TABLE 1.

Average weights ($N = 6$) of the adductor muscle, gonad, total tissue and whole organism (shell + tissues) from lagoon and post-transport.

	Adductor Muscle (g)	Gonad (g)	Total tissue Weight (g)	Total Weight (g)
Scallops from lagoon	7.0 ± 1.8 ^a	2.5 ± 0.7 ^a	21.6 ± 4.5 ^a	61.0 ± 12.2 ^a
Scallops post-transport	7.2 ± 1.5 ^a	2.0 ± 1.3 ^a	17.9 ± 3.2 ^a	60.5 ± 9.8 ^a

Data represent the mean and standard deviation of $n = 6$

Different letter in the same column indicates significant differences ($P < 0.05$)

TABLE 2.

Means \pm SD of total carbohydrates, glycogen, ATP, ADP, AMP and calculated AEC levels in the adductor muscle of lion's paw scallop (*Nodipecten subnodosus*) before and after transport.

	Total Carbohydrates (mg/g)*	Glycogen* (mg/g)	ATP (μ M/g of Muscle)	ADP (μ M/g of Muscle)	AMP (μ M/g of Muscle)	AEC	Muscle Yield Index (%) ²
Scallops from lagoon	243.4 \pm 25.6 ^a (203.6–268.5)	230.1 \pm 24.7 ^a (201.4–253.0)	7.4 \pm 2.2 ^a (4.9–10.6)	2.3 \pm 1.0 ^a (1.5–4.1)	0.6 \pm 0.4 ^a (0.17–1.3)	0.8 \pm 0.1 ^a (0.70–0.91)	32.2 \pm 5.7 ^a
Scallops post-transport	15.4 \pm 7.1 ^b (8.0–24.5)	12.6 \pm 6.6 (6.1–22.4)	3.7 \pm 1.8 ^b (0.8–5.6)	3.7 \pm 1.1 ^b (2.6–5.54)	3.9 \pm 2.0 ^b (1.64–5.89)	0.5 \pm 0.2 ^b (0.2–0.7)	40.4 \pm 5.8 ^b

The values are the mean \pm SD of $n = 6$.

Different letter in the same column indicate significant differences ($P < 0.05$)

adapted with an oximeter and a thermometer. Ice bags were placed inside the cooler, then sealed with a rope and filled with O₂. organisms from the lagoon, before and after shipping, were frozen in liquid nitrogen. Average weights for adductor muscle, gonad total tissue and total weigh of the scallop are shown in Table 1. No significant changes ($P > 0.05$) were observed between the organisms before and after transportation, however a slight change was observed in the total tissue weight caused by the liberation of water from the mantle, this fact needs to be considered in more detail in further studies. Table 2 shows the average levels of glycogen content, total carbohydrates, ATP, ADP, AMP, adenylic energetic charge and muscle yield index of the adductor muscle of lion's paw scallop from lagoon and post-transport. A significant decreased ($P < 0.05$) in the glycogen content, total carbohydrates,

ATP and adenylic energetic charge was observed after transport, because these compounds are used by the organisms to compensate the stress produced during the transport and maintain the good operation of their organs. On the other hand, the ADP and AMP concentrations as well as the muscle yield index increased significantly ($P < 0.05$) because of breakdown of ATP, which produces the accumulation of ADP and AMP and the liberation of water, respectively. Finally, Table 3 shows the free amino acid composition in the adductor muscle of lion's paw scallop and the effect of transportation on their concentration. Glycine, taurine, arginine and alanine were the most dominant free amino acids and accounted for 74.2% of the total. After the transport, a significant increase ($P < 0.05$) in the concentration of free amino acids (individual and total) was observed. This increase was produced by the dehydration during the transportation, since free amino acids, which are important in maintaining normal physiological and biological functions, are used together with potassium, bicarbonate and phosphate compounds as osmotic effectors in marine bivalves. In conclusion, the method used to transport the organisms was successful due to the high rate of survival (88 %) and the quantity of the transported organisms

TABLE 3.

Free aminoacids—Initial and post-transport composition of free amino acids in the adductor muscle of *Nodipecten subnodosus*.

Amino Acid	(mg/100 g of Muscle) Scallop From Lagoon	Post-transport
Glycine	1454.8 \pm 310.3 ^a	1540.8 \pm 139.0 ^a
Taurine	761.1 \pm 163.8 ^a	764.6 \pm 65.4 ^a
Arginine	337.0 \pm 82.2 ^a	797.6 \pm 94.9 ^b
Alanine	225.1 \pm 81.3 ^a	129.1 \pm 45.0 ^b
Glutamic acid	141.0 \pm 27.1 ^a	138.6 \pm 28.0 ^a
Histidine	110.3 \pm 49.7 ^a	126.4 \pm 57.7 ^a
Aspartic acid	72.1 \pm 25.1 ^a	76.2 \pm 33.7 ^a
Threonine	61.1 \pm 15.5 ^a	201.6 \pm 36.7 ^b
Serine	25.8 \pm 11.4 ^a	127.6 \pm 33.6 ^b
Lysine	25.4 \pm 7.3 ^a	137.6 \pm 50.2 ^b
Valine	23.9 \pm 7.4 ^a	112.9 \pm 36.8 ^b
Phenylalanine	13.3 \pm 3.5 ^a	111.7 \pm 37.5 ^b
Tyrosine	12.8 \pm 4.3 ^a	111.2 \pm 26.8 ^b
Leucine	10.8 \pm 2.8 ^a	137.1 \pm 47.7 ^b
Methionine	8.4 \pm 4.1 ^a	46.2 \pm 16.7 ^b
Isoleucine	8.2 \pm 1.9 ^a	93.9 \pm 51.9 ^b
Total (mg/g of muscle)	3637.7 \pm 919.6	4353.2 \pm 459.1

The values are the mean \pm SD of $n = 6$.

GREAT SCALLOP MYOSTATIN—THE ROLE AS A NEGATIVE MUSCLE GROWTH REGULATOR ALSO IN INVERTEBRATES? H. Pagander,¹ O. Strand,² T. Magnesen,³ I. A. Johnston⁴ and O. Andersen.¹ ¹AKVAFORSK, P.O. Box 5010, 1432 Ås-NLH; ²Inst. Marine Research, P.O. Box 1870 Nordnes, N-5817 Bergen; ³SCALPRO AS, 5337 Rong; ⁴Gatty Marine Laboratory, University of St. Andrews, Scotland.

Cultivation of scallop has received much attention because of the increasing demand for high quality seafood products at the European market. The highly favorable conditions for growing the great scallop, *Pecten maximus*, along the Norwegian coastline give a unique opportunity to become a leading nation for scallop production. This project is focusing on the environmental and genetic regulation of the larval growth and development of the large adductor muscle, which is the primary product sold. The muscle fiber

anatomy and recruitment in molluscs have been studied for the first time. Water temperatures of 14°C or 18°C at early developmental stages were shown to influence larval growth and survival. Genes encoding contractile proteins and regulatory factors have been partially isolated, including the negative muscle growth regulator myostatin. Great scallop myostatin showed about 50% sequence similarity to fish and mammalian myostatin in the active C-terminal portion. The construction of an EST-library from the scallop adductor muscle is in progress to reveal the full-length cDNA sequences of additional muscle regulatory genes. *In situ* hybridization and immunohistochemistry will then be used to study the sub-cellular location of the gene products during growth and recruitment of the muscle cells.

ADOPTING AREA-BASED HARVESTING STRATEGIES IN THE TASMANIAN SCALLOP FISHERY. Rod Pearn and Hilary Revill. Department of Primary Industries, Water and Environment, Tasmania, Australia.

The Tasmanian scallop fishery is primarily based on the harvest of the commercial scallop (*Pecten fumatus*). Scallop fisheries worldwide are notorious for their variability in recruitment. The Tasmanian fishery is no exception to this, and historically, the fishery has been subject to highly variable annual catches and total fishery closures. The fishery has only opened in a total of 6 years in the last decade. The high variability in stock abundance is strongly influenced by environmental factors. In 2003, the fishery adopted a "tight" spatial management strategy with the aim of increasing the likelihood of fishing continuity between years. The strategy is different from the majority of other fisheries in that all areas are closed unless specifically opened. The strategy limits fishing to discrete areas and aims to:

- maximize stock rebuilding in unfished areas
- protect stock in other areas for future access
- limit fishing impacts on under size scallops
- limit fishing impacts on the broader marine environment

Seasonal closures are in force during the period when spawning and larval settlement are likely. The closed season also protects newly settled scallops.

The spatial management system also incorporates 3 levels of closure.

- Permanent closed areas: notably all shark refuge areas are closed to scallop dredge activities.
- Closed Area (class 1) areas may be declared prohibiting all vessels with a scallop dredge or active scallop license being in an area, including transiting the area. This type of closure maximizes the protection of scallops, especially where they are in close proximity to open areas.
- Closed Area (class 2) areas are all other state waters not design-

nated, as open. Scallop vessels can transit these areas, however cannot scallop fish or have any scallop dredge in the water. All vessels participating in the scallop fishery are required to have a vessel monitoring systems (VMS), which allows real time monitoring of vessel positions.

Generally, before any area is considered for opening a survey is conducted either by permit or by scientific assessment. An area may be considered for opening if there are substantial scallop beds the area consisting of less than 20 % undersize scallops.

Previous survey information, past history and anecdotal information maybe used to determine where the survey will be conducted. The Spatial management system where the majority of waters a closed in to fishing, however presents challenges in identifying scallop beds outside open areas. Potentially this either increases research costs or limits information. The need for increased spatial information has been identified as a major challenge by industry and the management agency. Over the last 2 years various forms of industry based surveys have been trialed, with the aim of increasing information about the scallop resource. The need for stock information on a wider geographical scale to determine future harvesting strategies and incentives to encourage fishers to conduct surveys will be discussed.

A NEW METHOD OF DEPLOYING COLLECTORS IN AREAS WITH FISHING ACTIVITIES. Juan B. Peña, Maria J. Diez, and Carlos Saavedra. Instituto de Acuicultura Torre de la Sal (CSIC), E-12595 Ribera de Cabanes, Castellón, Spain.

We previously found a natural population of the Mediterranean scallop *Pecten jacobaeus* L. in an area between 50-m and 100-m depth in Castellón waters (Western Mediterranean). This is a fishing bed for some economically important fish species that are living on the sand and mud bottom around some rocky formations. However, there is a big rocky ground at a depth of 60–69 m where fishing boats do not fish. The main problem we have had in the last years is regarding the cutting of some of the collector's surface buoys by fishermen or curious people. The aim of this study is to improve and assure scallop collectors during the 7 months of settlement near the bottom. The surface water temperature in Castellón reaches 26°C to 27°C during summer, and usually collectors are removed in October to November, when the water temperature decreases to 18°C to 20°C. Until now the standard collector line has a surface buoy and a weight in the end of the rope to keep it tense. Bags are attached near the weight. In this study we compared the standard collector line with a new collector line formed by a rope of 90 m that had a weight on both ends and some small subsurface buoys in the central part of the rope. This new design kept a curved form with the upper arch at approximately 48 m from the sea surface. In this way, fishermen cannot see the buoys and the presence of collectors. A series of 14 collector bags sepa-

rated 70 cm between them and 3 m from the weight were attached to the rope. The strings of collectors were positioned April 30 and retrieved November 28, 2004. The collector lines were placed on the rocky bottom and their geographical position registered by a (global positioning system) GPS. In November the geographical position of each line was detected by the GPS and the boat sonar; then, collector lines were retrieved by an iron gadget with many spikes in order to catch the submerged curved rope. Seven species of pectinids were identified from the collectors. The most abundant was *Aequipecten opercularis* (55.5%), but other species were present and scarce. Most of them were without commercial value: *Crassadoma multistriata* (2.1%), *Mimachlamys varia* (0.1%), *Paltilium incomparabile* (32.7%), *Perupecten commutatus* (0.2%) and *Pseudamussium clavatum* (4.4%), with the exception of the king scallop *Pecten jacobaeus* (4.9%). Other species of bivalves were identified and counted, because of their number and size inside the bag: *Pteria hirundo* (18%) and *Atrina fragilis* (2.7%), but small-sized bivalves, were rejected without being counted. No significant differences were observed between the spat settlement on the standard collectors and the new collector, because both had 14 bags and were placed in the same area at the same time. The pectinid spat number per collector bag was on average 60.2 *Aequipecten opercularis* and 5.3 *Pecten jacobaeus* on the standard collectors and 60.8 and 5.5 on the arched collectors. The mean size of *Aequipecten opercularis* spat on standard collectors was 17.34 ± 0.19 mm (range 10.5 to 27.2 mm) and on the arched collectors was 16.87 ± 0.11 mm (range 8.5 to 29.9 mm). The mean shell height of *Pecten jacobaeus* spat was 17.46 ± 0.41 mm (range 9.3–24.5 mm) and 17.15 ± 0.28 mm (range 7.9–26.6 mm), respectively. The new method of deploying collectors gave a similar settlement of scallop spat than the standard collectors, but the novelty is in the placement without surface buoys and the retrieval by means of GPS and sonar. Therefore, the new arched line collector is a good method for catching pectinid spat in areas where the surface buoys from the collector strings can be cut or stolen by fishermen or curious sport fishermen, or even, by coast guards that think the ropes may contain drugs or other contraband goods.

REPRODUCTION OF *NODIPECTEN SUBNODOSUS* (SOWERBY, 1835) IN SUSPENDED CULTURE IN THE GUERRERO NEGRO LAGOON, BAJA CALIFORNIA SUR MEXICO. E. Pérez-DeLeón,¹ M. Arellano-Martínez² and B. P. Ceballos-Vázquez.² ¹Universidad Autónoma de Baja California Sur; ²Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional, La Paz, B.C.S., México

Knowledge of the reproductive cycle of economically important marine invertebrates is basic to culture activities and management of natural stocks. Since 1997, an increasing interest in this species was observed especially because of its high potential for aquaculture. Documentation of the reproductive biology of *N. sub-*

Figure 1. Reproductive cycle of *Nodipecten subnodosus* in suspended culture system in the Guerrero Negro lagoon, B.C.S. Mexico.

nodosus is scarce (Reinecke-Reyes 1996, Racotta et al. 2003, Arellano-Martínez et al. 2004). This study analyzes the reproduction time of *N. subnodosus* in suspended culture conditions in the Guerrero Negro lagoon at its northern geographical limit of distribution. Lion's paw scallop spat produced in the hatchery laboratory of Centro de Investigaciones Biológicas del Noroeste in La Paz B.C.S., Mexico were used in the study. In August 2001, 2-month-old scallops (≈ 3 mm in shell height, HL) were seeded in the Guerrero Negro lagoon ($27^{\circ}56'$ and $28^{\circ}06'N$ and $114^{\circ}02'$ and $114^{\circ}09'W$). Nestier cages were suspended at 6-m depth near the bottom. Density was adjusted to maintain free the 50% of tray. HL of the scallops was registered at roughly monthly intervals over a period of 19 months. Since February 2002, between 5 to 12 scallops were sampled randomly each month. Gonads of these scallops were fixed in a 10% formalin solution for histological analysis. Additionally, water temperature and chlorophyll *a* concentration were recorded at each sampling time. Although there were no samples in all months, the tendency observed in the reproductive cycle (Fig. 1) agreed with previous reports for *N. subnodosus* (Reinecke-Reyes 1996, Racotta et al. 2003, Arellano-Martínez et al. 2004). It showed a clear seasonality related to the water temperature, ripening when temperature began to increase (April, $18^{\circ}C$). Spawning occurs with high concentration of chlorophyll *a* and when temperature started to decrease (September) (Fig 2). The histological analysis shows that the first gonad development

Figure 2. Monthly variation in water temperature and chlorophyll *a* concentration in the suspended culture system in the Guerrero Negro lagoon, B.C.S. Mexico.

Figure 3. Average shell height reached at each sampling date in the suspended culture system in the Guerrero Negro lagoon, B.C.S. Mexico.

started when mean shell height was 50 mm (April, 9 months old). The earlier mentioned agreed with observations in other areas on the Pacific coast. In a wild population from Ojo de Liebre lagoon (adjacent to Guerrero Negro lagoon) scallops started the gonad development at 51-mmHL (8 months old, approximately) (Arellano-Martínez et al. 2004). In a culture system in Bahía Magdalena the gonad development started in scallops at 52-mmHL (9 months old) (Racotta et al. 2003). On the other hand, the gonad development coincided with a period of minimum increment in shell height (Fig 3), probably because the energy now is channeled to reproduction more than growth. According to the earlier mentioned and considering that *N. subnodosus* reaches large sizes (218-mmHL), it is evident that the lion's paw scallop is reproductively precocious with early gonad development before the first year of age.

CHARACTERIZATION OF THE IMMUNE RESPONSE OF THE LION'S PAW SCALLOP *NODIPECTEN SUBNODOSUS*. Erick R. Ramírez-Castillo,¹ Bertha P. Ceballos-Vázquez,¹ Antonio Luna-González² and Marcial Arellano-Martínez.¹ ¹Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional, La Paz, B.C.S. México; ²Universidad Autónoma de Baja California Sur, La Paz, B.C.S. México.

The hydrolytic effects of the different lysosomal enzymes are one of the most important mechanisms in the degradation of pathogenic organisms inside or outside the hemocytes in bivalve mollusks. Therefore, the enzymatic activity in hemolymph has been extensively studied as indicator of the immune capacity in many species of bivalves. The objective of this work is to analyze the immune response of the lion's paw scallop *Nodipecten subnodosus* to the challenge with *Vibrio alginolyticus* strain APSA2, through the characterization of the enzymatic activity (lysosomal enzymes). Before the experiment it was necessary to determine the sublethal dose of *V. alginolyticus*. It was determined using 5 lots with 8 organisms each one and testing 5 concentrations from 10^2 to 10^6 UFC/mL during a period of 10 days. Another lot served as control, which was injected with saline solution. The sublethal dose was established at 10^5 UFC/mL. Then, 5 lots of 6 organisms were injected with the sublethal dose (10^5 UFC/mL) and 4 organisms served as control by treatment using saline solution. Samples of 6 mL of hemolymph were obtained from the adductor muscle using a 5 mL sterile syringe after 6 and 24 h and 3, 6 and 10 d. In each case, hemocytes were quantified (hemocytes/mL) with a hemacytometer. Additionally, the diameter of the hemocytes was obtained using the SigmaScan Pro software (Version 5.0). To separate the hemocytes from the plasma the hemolymph was centrifuged at $\times 500g/10$ min/ $4^\circ C$. Once separated, they were resuspended and washed in buffer Tris HCl pH 6.5. Then hemocytes were broken by freeze-thaw to obtain the supernatants (HLS) of the cellular debris. Hydrolytic enzymes were determined in plasma and HLS with the API ZYM kit (BioMérieux) and lysoplate assay. Enzymatic activity was reported in relation with the protein con-

TABLE 1.

centration of samples. The concentration of protein was determined by the Bradford method. The samples of each time were pooled taking 400 μ L/sample. The ANOVA was used to assess significant differences between times. To compare the quantity of hemocytes, the mean of all controls was obtained. The quantity of hemocytes was significantly lower (ANOVA, $P < 0.05$) 6 h after challenge, whereas the hemocytes were significantly larger (ANOVA, $P < 0.05$) (Fig. 1). The quantity and diameter of hemocytes in treatments were negative and significantly correlated ($r = -0.82$, $P < 0.001$). Of the 19 enzymes detected by the API ZYM kit, only 11 can be characterized in SLH and 5 in plasma (Table 1). The enzymatic activity was significantly higher (ANOVA, $P < 0.05$) in hemocytes than in plasma. The enzymes with higher activity were esterase and leucyl arylamidase in both, SLH and plasma. Lysozyme-like activity did not show significant differences (ANOVA, $P < 0.05$) between the sampling times. However, in plasma the lysozyme-like activity was significantly higher than in HLS. The infection was controlled in almost all bacterial concentrations. However, the concentration of 10^6 UFC/mL exceeded the capacity of immune response producing a total mortality of scallops 72 h after challenge. With the sublethal dose (10^5 UFC/mL) at 6 h, 3 d, and 6 d, animals showed lower hemocyte numbers. This may be due to their lysis and/or movement into tissues (diapedesis) provoked by bacteria while fighting infection. However, at 24 h hemocyte number was higher than the control and cell diameter was lower. It seems that hematopoiesis was induced by the bacterial infection because it could be seen by the number and hemocyte diameter. Hematopoiesis had been wound-induced in the pearl oyster *Pinctada fucata martensii*, where proliferation occurs in the connective tissues of the stomach and intestine. On the other hand, the enzymatic activity determined by the API ZYM kit did not show a clear tendency. Enzymes with higher activity, esterase and leucyl arylamidase, are the responsibility of the change in the conformation of the cell wall of the bacteria. Also, lysozyme acts destroying the bacterial cell wall, making the bacterial degradation easier. Lysozyme-like activity was higher in plasma than in hemocytes, especially in the treatments with bacteria. The higher enzyme concentration in plasma suggests that lysozyme was released from hemocytes into plasma during the pathological stress caused by *V. alginolyticus*.

COMPARATIVE GROWTH OF THREE SCALLOP SPECIES IN MEXICO—(*ARGOPECTEN VENTRICOSUS*, *NO-DIPECTEN SUBNODOSUS* AND *EUVOLA* = *PECTEN VOGDESI*). César A. Ruiz-Verdugo¹ and Miguel Robles-Mungaray.² ¹Laboratorio Experimental de Acuicultura, Departamento de Ingeniería en Pesquerías, Universidad Autónoma de Baja California Sur, Ap. Postal 19-B, La Paz, Baja California Sur, México, 23000; ²Sea Farmers S.A de C.V., Av Obregon # 525 pte. col centro, Los Mochis, Sinaloa, México.

In the past years, efforts have been made in Mexico to diversify aquaculture of marine bivalves, especially scallops. Several studies in the past 15 years have focused on the culture of the Pacific

calico scallop (*Argopecten ventricosus*, Sowerby II, 1842), however, only a single company in the state has been successful in producing commercial quantities over a long time period. One of the principal limitations for the culture of the Pacific calico scallop is its small size (up to 60–80 mm), this implies that large amounts of organisms must be grown, and that the commercial value of the meats is low in comparison to species with larger adductor muscles. In addition to the Pacific calico scallop, there are two species of pectinid of commercial importance in Mexico, the lion's paw scallop (*Nodipecten subnodosus*) and the flying scallop (*Euvola* = *Pecten vogdesi*), which are larger (*N. subnodosus* up to 250 mm and *P. vogdesi* 130 mm) and therefore reach higher market values. *N. subnodosus* is one of the largest pectinids worldwide, and some basic growth studies and feasibility of different culture methods have been done in the past years. For *E. vogdesi* only little information exists. No comparative analysis of growth of all three species under the same culture conditions has as yet been undertaken. Therefore, this study attempts to compare growth of the three native pectinids under cold conditions in Magdalena Bay and warm water conditions in La Paz Bay. The spat of *Argopecten ventricosus* and *Nodipecten subnodosus* was produced in the Laboratory of Larviculture CIBNOR (Biological Research Center of the Northwest, S.C. La Paz, B.C.S.). The juveniles of Pacific calico and Lion's paw scallop averaged 17.0 mm and 19.0 mm shell height respectively. The spat of *Euvola vogdesi* was produced in the Laboratory of Experimental Aquaculture at the University of Baja California Sur (UABCS) and averaged 16.0 mm shell height at the beginning of the experiment. The spat was cultured in 2 sites, Rancho Bueno (Magdalena Bay) and Pichilingue (La Paz Bay) (Fig. 1). Oyster trays suspended from a long line were used to culture the organisms, 40 organisms of each one of the three species of pectinid were placed in the same tray, using the replicates total. Growth and survival was measured monthly from February to June of 2002. On each occasion, shell height of 30 organisms of each species was height measured using a digital vernier (± 0.01 cm). Results of this experiment are shown in Figure 2. *N. subnodosus* shows higher growth at both culture sites. The best growth for all three species was reached in Magdalena Bay,

Figure 2. Growth of *Euvola vogdesi*, *Argopecten ventricosus* and *Nodipecten subnodosus* cultures in Magdalena Bay and La Paz Bay. Means at month are indicated with their standard errors.

where lower temperatures and a higher primary productivity are found than in La Paz Bay. Final average size was 55.02 ± 0.45 mm for *N. subnodosus* 46.61 ± 0.58 mm for *E. vogdesi* 43.8 ± 0.45 mm for *A. ventricosus*. The breeders of *N. subnodosus* and *A. ventricosus* came from the Pacific side of the Peninsula while breeders of *E. vogdesi* were from the Gulf of California. The results show that *N. subnodosus* and *E. vogdesi* are the most promising species for aquaculture development in the region. It is necessary to study the culture of *E. vogdesi* in the Pacific and of *N. subnodosus* in the Gulf of California, and to evaluate whether lion's paw spat resulting from breeders of the Gulf of California, shows better growth and survival under warm water conditions than organisms originating from the Pacific population.

INFLUENCE OF DEPTH ON GROWTH AND SURVIVAL OF THE LION'S PAW SCALLOP *NODIPECTEN NODOSUS* (LINNAEUS, 1758) IN SOUTHERN BRAZIL. Guilherme S. Rupp,¹ Gilberto C. Manzoni,² Micheline M. de Bem,³ Lin H. L. Iwersen,³ Celso C. Buglione Neto³ and Erich Cerchiari.²

The Atlantic lion's paw scallop, *Nodipecten nodosus*, is the largest pectinid occurring in Brazilian waters and is considered a prime candidate species for aquaculture due to its size and commercial value. Whereas there are studies on the effects of environmental factors affecting growth and survival during nursery culture (Rupp et al. 2004a, 2005), little information is available about the growout phase in Brazil. An understanding of the effects

Figure 1. Cultivation area on Baja California Peninsula.

TABLE 1.

Mean shell height, adductor muscle wet weight, total somatic tissue wet weight, dry weight of fouling and percent survival (January 2005).

Depth	Shell Height (mm) (95% CI)	Adductor Muscle Wet Weight (g) (95% CI)	Total Somatic Tissue Wet Weight (g) (95% CI)	Dry Weight of Fouling (95% CI)	% Survival
3 m	70.19 (3.8)	9.80 (1.2)	21.93 (2.6)	17.3 (2.2)	82.2
9 m	63.79 (2.3)	6.04 (1.1)	13.97 (2.3)	10.7 (1.4)	84.1

of environmental factors associated with depth is essential to establish optimized culture strategies and therefore the basis for commercial aquaculture. This study was carried out to compare the effects of a wide array of environmental factors associated with depth on growth and survival of *N. nodosus* cultured in Santa Catarina State, Brazil. *Nodipecten nodosus* (Linnaeus, 1758) juveniles were hatchery-produced and transferred to sea-based nursery using techniques described by Rupp et al. (2004b, 2005). When a mean shell height of 18 mm was attained (February 2004), scallops were suspended on a sub-surface long-line at 3 and 9 m in triplicate lantern-nets at each depth. The experiment was carried out at a coastal aquaculture site (Armação de Itapocoroy) (26°46'S to 48°37'W), in Santa Catarina State, Brazil. Lantern nets were replaced on a monthly basis when live scallops were also counted and measured for shell height. Every other month a sample of 12–15 scallops/net were transferred to the laboratory for measurement of somatic and reproductive growth, as well as quantification of fouling organisms settled on the shells. Temperature was recorded hourly and Chlorophyll *a*, total seston, particulate organic matter, particulate inorganic matter and dissolved oxygen were measured twice a month. In May 2004, because of a large variation

TABLE 2.

Mean temperature, salinity, concentration of chlorophyll (*a*), PIM, POM, % PIM and turbidity.

Depth	Temp (°C)	Salinity ‰	Chlorophyll (<i>a</i>) (µg/L)	PIM mg/L	POM mg/L	% PIM	Turbidity NTU
3 m	22.6	33.78	2.77	3.35	0.95	75.8	2.73
9 m	22.3	34.31	2.8	6.83	1.16	84.6	5.13

in size and to mimic commercial operations, scallops were size-graded and those smaller than 22 mm were separated in different nets. The larger group was maintained at their respective depths in triplicate nets. Results are presented for the larger group of scallops grown from May 2004 to January 2005. Mean shell heights of the larger group in May 2004 were 40.61 mm and 37.28 mm at 3 and 9 m respectively, which were statistically similar (Anova, $P < 0.01$). The mean number of scallops per lantern net was 243 at 3 m and 234 at 9 m, which represented 58% and 57% respectively of the total number of scallops before size selection. Table 1 shows the mean shell height, adductor muscle wet weight, total somatic tissue wet weight, and dry weight of fouling settled on shells, recorded after 8 months of suspended culture (January 2005). Percent survival was determined in relation to the number of scallops after size selection (May 2004). Table 2 shows the mean temperature, salinity, concentration of chlorophyll *a*, PIM, POM, % PIM in relation to total seston and turbidity. Figures 1 and 2 show the growth curves in shell height and adductor muscle wet weight, respectively. Growth was least at 9 m, where higher turbidity and higher PIM were recorded. A commercial size adductor muscle (mean wet weight of 6 g) was attained in September 2004 at 3 m, whereas at 9 m, it was only attained 4 months later.

Figure 1. Shell height.

Figure 2. Adductor muscle wet weight.

MOLECULAR PHYLOGENETICS OF AMERICAN PECTINIDS. Carlos Saavedra and Juan B. Peña. Instituto de Acuicultura de Torre la Sal-CSIC. Ribera de Cabanes, E-12595 Castellón, Spain.

Pectinids are one of the most conspicuous families of Bivalves living in the sea. In spite of its abundance and economic importance, the taxonomy and systematics of pectinids is not well known. Several different taxonomic classifications below the family level have been proposed in the past, most of them based on shell features of adult individuals. In a collection of papers, Waller argued that these were not good characters for taxonomy, and based his classification in features of the larval shell. He proposed that the family could be divided into 2 subfamilies, pectininae and chlamydiae. The problem of the classification of pectinids has been recently approached with the tools of molecular phylogenetics. Matsumoto and Hayashi (2000) studied a fragment of the mitochondrial cytochrome oxidase gene in 17 species. His analysis was based on amino acid sequences, and supported the existence of the two subfamilies proposed by Waller. Barucca et al. (2004) published a study of 23 species (16 genera), based on ca. 1000 nucleotides of the mitochondrial large and small ribosomal RNA subunits, supporting that subdivision as well. Most of the species studied by Matsumoto and Hayami were from the west Pacific, whereas most of the species studied by Barucca et al. were from other regions, mainly Europe. American species were poorly represented (3 species in Barucca et al.'s study, of which only one was exclusive of the American continent; 1 non-exclusive species in Matsumoto and Hayami's study). However, the American continent has a very specific pectinid fauna, with several exclusive genera. Many of these species have commercial interest as well. The phylogenetic relationships of these genera and species and its evolutionary history has been studied from a morphological and paleontological perspective, but rarely from a molecular phylogenetics perspective. A molecular phylogenetic study of these genera and of its relationships with pectinids from the other continents is highly desirable. Here we present a phylogenetic analysis of 10 American species belonging to 6 different genera: *Argopecten gibbus*, *A. purpuratus*, *A. ventricosus*, *Euvola ziczac*, *E. vogdesi*, *Hinnites giganteus*, *Nodipecten nodosus*, *N. subnodosus*, *Placopecten magellanicus* and *Zygochlamys patagonica*. We scored the same 16 S and 12 S ribosomal gene regions studied by Barucca et al., which allowed us to conduct a phylogenetic study of these taxa in the context of the world pectinid fauna.

BENTHIC RICHNESS IN SCALLOP BEDS—*ZYGOCHLAMYS PATAGONICA* (KING AND BRODERIP, 1832) AS PRIMARY SETTLEMENT SUBSTRATE. Laura Schejter and Claudia Bremec. INIDEP, Instituto Nacional de Investigación y Desarrollo Pesquero, Paseo Victoria Ocampo 1, 7600, Mar del Plata, Argentina.

The availability of a suitable substratum is one of the critical factors for the colonization of sessile species. Mollusc shells, decapod carapaces and sea urchin spines are several frequent surfaces used as hard substrata available for settlement of sessile organisms in soft bottoms. Epibiosis is the scientific name for this aquatic phenomenon of a non-symbiotic association between epibionts (organisms growing attached to a living surface) and basibionts (substrate organisms that are hosts to the epibionts) (Wahl 1989). Previous works on *Zygochlamys patagonica* (Diehl 1977, Walossek 1991, Rosso & Sanfilippo 1991, Sanfilippo 1994, Bremec & Lasta 2002, Bremec et al. 2003) mentioned a great variety of organisms, including calcareous algae, poriferans, hydrozoans, anthozoans, polychaetes, molluscs, cirripeds, foraminiferans, ascidians and bryozoans. This study summarizes available and new information of epibionts on *Zygochlamys patagonica* and assesses the contribution of this basibiont to increasing the species richness in scallop beds in the Argentine Sea. The checklist of epibionts is given. We compiled information from the bibliographic sources earlier cited that refer to epibionts on Patagonian scallops. Additionally, we give new results from material collected during monitoring cruises (INIDEP) carried out during 2001 (Hydrozoa, G. Genzano, pers. comm.) and 2003 (Porifera, Schejter et al. in prep., Polychaeta & Ascidacea, pers. observ.). The study area comprises between 39° S and 47° S in the Argentine Sea, along the 100-m isobath and in the north-patagonian coast (90–110 m) and the Magellan Strait (80m, 53°S). A total of 35 epibiont taxa was registered on *Zygochlamys patagonica* valves (Table 1). The presence of the sponge *Hymedesmia* (*Stylopus*) *longurius* (Hentschel, 1914) is a new record for the Argentine Sea, the species was only known for Antarctic waters (Schejter et al., in prep.). The hydroids *Lafoea fruticosa* (M. Sars, 1851) and *Phiallela chilensis* Hartl. 1905 were found as secondary level epibionts (epibionts of other *Z. patagonica* epibionts, mainly other hydroids). Other epizoeic organisms were small isopods and amphipods, found as free living organisms between the crevices developed by the association of epibionts. The mollusc *Calyptrea pileolus* (d'Orbigny, 1841) and the sea cucumber *Psolus patagonicus* (Eckman, 1925) were closely associated to the scallop valves, and unidentified small egg capsules of gastropods were also occasionally found (personal observation).

A total of 82 species were identified in the Patagonian scallop assemblage in the Argentine Sea, including the deeper fishing grounds along the 100 m isobath and the coastal north-patagonian beds Sea Bay and Tres Puntas, 16 of which were indicated as scallop epibionts (Bremec & Lasta 2002). This region is characterized by soft bottoms and the scallops constitute the available

hard substrate for the settlement of sessile invertebrates; at least 33 taxa are mostly epibionts on scallops according to our results. Green algae and barnacles only encrusted scallops from the Magellan Strait (Rosso & Sanfilippo 1991, Sanfilippo 1994). It is remarkable that recruits of Patagonian scallops only settled on living scallops (Bremec et al. 2003, Bremec & Schejter this Workshop), as well as the other epibionts listed in Table 1. Free shells provided substrate to egg capsules of *Fusitriton magellanicus* Rodding, 1798, *Odontocymbiola magellanica* Gmelin, 1791 and *Adelomelon ancilla* (Solander, 1786) (Bremec et al. 2003) and occasionally sponges. Among other frequent and conspicuous organisms of the benthic assemblage, the spider crab *Libinia* *granaria* (Schejter & Spivak, in press), the gastropods *Fusitriton magellanicus*, *Odontocymbiola magellanica* and *Adelomelon ancilla* presented encrustations, not all taxa shared with scallops

(pers. obs.). It is known that most of the epibiont species in the world are not species-specific (Wahl & Mark 1999) even though epibionts are almost restricted to scallop valves in the Patagonian scallop beds. The contribution of *Zygochlamys patagonica* to increasing the benthic species richness is greatly favored by its dominance, both in abundance and biomass.

BENTHIC COMMUNITY ASSEMBLAGE ASSOCIATED WITH THE PATAGONIAN SCALLOP FISHERY IN RECLUTAS BED, 39°S, ARGENTINA, BETWEEN 1998 AND 2003—COMPARISON OF DISTURBED AND UNDISTURBED AREAS. Laura Schejter, Claudia S. Bremec and Daniel Hernández. INIDEP, Instituto Nacional de Investigación y Desarrollo Pesquero, Paseo Victoria Ocampo 1., 7600. Mar del Plata. Argentina.

Fishing provokes the removal of a huge biomass of target and non-target species. Trawling or dredging over the marine bottom produces an important effect on the ecosystem, damaging not only

the substrate but also the invertebrates associated with the bottom. These modifications could cause destruction of the benthic habitat and long and short-term changes in the composition and structure of the associated fauna (National Research Council, 2002). The Patagonian scallop, *Zygochlamys patagonica* (King & Broderip, 1832), is distributed in the Magellanic Biogeographic Province, and it is the target species of a recent fishery in Argentina along the 100 m isobath (Lasta & Bremec 1998). The Reclutas bed is located between 39°00'–39°30'S and 55°45'–56°05'W. An exclusion area (39°20'–39°30'S and 55°52'–56°00'W, not allowed to commercial fishing) was established inside this bed in 1996. The aim of this study is to compare the composition and structure of the assemblage in the scallop bed Reclutas, in areas subjected to fishing effort and in the exclusion area, between 1998 and 2003, in order to identify short-term faunistic changes. A total of 83 samples were collected at Reclutas bed during assessment research cruises (R/V Capitán Cánepa, INIDEP) in 1998, 2001, 2002 and 2003, with a non-selective dredge of 2.5 m wide (efficiency 43%; Valero, 2002) following a sampling design of stations spaced regularly at 5 nm intervals. Additionally, 8 samples in 1998, 6 in 2001, 9 in 2002 and 3 in 2003 were also taken in the exclusion area of the same bed. Identification of organisms, abundance and biomass data were obtained on board (1998 and 2001) and at the laboratory (2002 and 2003). Data indicate abundances and biomasses of organisms per 100 m². Multivariate analysis (ANOVA, PRIMER software) was applied. Hierarchical and multidimensional analysis (Bray-Curtis similarity index, fourth root transformation) and SIMPER test were developed to establish similarity between stations and species assemblages. ANOVA was used to test differences between areas (fished-REX) and years (1998–2003); transformation " $\log(x + 1)$ " was used for biomass values. ABC curves were used to detect disturbance levels in all years and areas. Richness in the fishing area (F) ranged from 37 to 56 and number of taxa per station varied between 5 and 29, both varying in different years. In the exclusion area (REX), richness ranged from 23 to 40 and number of taxa per station varied between 8 and 25. Differences in richness are mainly due to differences in sampling effort (that was higher in the last 2 years) and to the expertise acquired in identification of taxa recorded. In general terms, echinoderms were always dominant in biomass both in F and REX. Four invertebrate taxa (*Austrocidaris canaliculata*, *Cosmasterias lurida*, *Ctenodiscus australis* and Porifera) were closely associated with the Patagonian scallop in every year and area studied, representing approximately 45% (or more) in biomass contribution (SIMPER analysis) to the community assemblage. The addition of other 7 common taxa (*Ophiactis asperula*, *Ophiacantha vivipara*, *Libidoclaca granaria*, *Actinostola crassicornis*, *Fusitriton magellanicus*, *Calyptaster* sp. and *Flabellum* sp.) increases the biomass contribution to approximately 70% (up to 80% in 1998 in F). ABC curves showed that F presented a moderately disturbed pattern in the 4 years, while REX, in 1998 showed a moderately disturbed area, but in 2002 biomass

curve is above abundance curve, in accordance with an undisturbed area. Bremec et al. (2000) found that at least eight samples are needed to get representation of most of the species in the Patagonian scallop benthic community. For that reason, samples from 2001 and 2003 in REX are not considered for the ABC analysis. Total biomass and scallop biomass in F differ significantly from REX considering all years (ANOVA: F = 5.491, $P = 0.021$ and F = 9.72, $P = 0.0023$, respectively). In both cases, biomasses were higher in REX. Faunal biomasses (excluding scallops) did not differ significantly between years or areas. In this study we found that the Patagonian scallop assemblage at Reclutas bed was persistent after 9 years of fishing activity, between 1995 and 2003 (see Bremec & Lasta 2002 for 1995 data). Changes in species richness detected since 1995, baseline condition, are attributed to the sampling procedure. Regarding comparisons between fished and non-fished areas, the total number of species was lower in the latter; but this could be attributed to the number of samples analyzed, what permits the occurrence of the majority of the species and also to the size of REX, which could make sampling the rare or occasional species difficult. ABC curves in REX, however, seem to show a recuperation of biomass in time. Short-term observations show differences in scallop biomass only between areas (F and REX); the fishing strategy carried out during the study period in Reclutas bed did not produce significant differences in the biomass of by-catch taxa.

SCALLOPS AND ALGAL TOXINS REVISITED. Sandra E. Shumway. Department of Marine Sciences, UCONN, 1080 Shennecossett Road, Groton, CT 06340, USA.

The interactions between scallops and toxic algae are complex and often unique to the algal species, scallop species and geographic region under consideration. In geographic regions where

only the adductor muscle has been traditionally marketed, algal toxins have not posed a significant threat to human health. In regions where both whole and “roe-on” scallops are consumed there is a need for careful monitoring of product. Recent increases in aquaculture and the marketing of whole scallops have rekindled the discussions on sequestering and biotransformation of algal toxins. There is a general increased awareness of the potential dangers of marketing and consuming whole scallops and consequently, more monitoring programs now include scallops as part of their regular sampling regimes. As scallop culture and the desire to market scallop parts other than the adductor muscle continue to expand globally, so will the need to establish comprehensive and affordable monitoring programs for algal toxins.

APPLICATION OF MULTIBEAM BATHYMETRY AND SURFICIAL GEOLOGY TO THE SPATIAL MANAGEMENT OF SCALLOPS (*PLACOPECTEN MAGELLANICUS*) IN SOUTHWEST NOVA SCOTIA. Stephen J. Smith,¹ Gerard Costello,² Vladimir E. Kostylev,³ Mark J. Lundy¹ and Brian J. Todd.³ ¹Department of Fisheries and Oceans, Invertebrate Fisheries Division, Bedford Institute of Oceanography, Dartmouth, Nova Scotia B2Y 4A2, Canada; ²Department of Fisheries and Oceans, Canadian Hydrographic Service, Bedford Institute of Oceanography, Dartmouth, Nova Scotia B2Y 4A2, Canada; ³Geological Survey of Canada (Atlantic), Natural Resources Canada, Bedford Institute of Oceanography, Dartmouth, Nova Scotia B2Y 4A2, Canada.

The management of scallop fisheries of the Scotian Shelf, Bay of Fundy and the Canadian side of Georges Bank currently include spatial components. Areas have been identified for seasonal closures to avoid gear conflicts, different size/meat weight or harvesting restrictions due to spatial variation in growth rates and closures to protect recently settled abundant year-classes. However, the development of reference points for harvest levels have generally taken a dynamic pool approach to their definition ignoring spatial patterns in abundance, age distribution, growth rates and settlement patterns. Recent work has identified large differences in growth rates within relatively short distances for scallop beds in the Bay of Fundy. Ignoring spatial heterogeneity of scallop populations ignores the fact that fishing also concentrates on spatial patterns reflecting growth rates and densities. Canada is committed to developing fine-scale maps of the bathymetry and surficial geology of its continental shelf areas to provide the basis for the management and conservation of the biological and mineral resources within its national jurisdiction. Bottom habitat maps developed from multibeam bathymetry, backscatter strength and geological sampling have been used by the offshore scallop industry to allocate fishing effort. The main advantages from using these maps

to the fishing industry has been to reduce fishing effort in areas that are marginal for scallops or difficult to tow gear in, increase overall catch rates by concentrating effort in areas identifiable as scallop habitat and reduce costs associated with fishing. However, these maps have not been used to develop fine-scale management plans that are attuned to the spatial heterogeneity of the scallop populations. Scallop grounds off of southwest Nova Scotia have recently been mapped using multibeam sonar technology in a joint project partnership of the Department of Fisheries and Oceans, Natural Resources Canada and the local scallop fishing industry. One of the major objectives of this project is to collect spatial information on scallop distribution, growth and size composition, bycatch data, as well as fine-scale bathymetry and surficial geology for the purposes of developing spatially based fisheries management plans. There are two phases for the work on this objective. In the first phase, multibeam backscatter strength data, geological and benthic sampling data will be used to develop habitat maps of the area. At the same time, spatial patterns of scallop growth, densities and size composition obtained from concurrent scallop drag surveys will be related to these habitat attributes. All of this information does not in itself determine what the objectives of spatial management are and the potential advantages of spatial management over the standard approach will be explored in the second phase of the project.

TOWCAM—TOWED CAMERA ARRAY FOR VIDEO/ STILL BENTHIC SURVEYS. Stephen J. Smith,¹ D. McKeown,¹ M. Lundy,¹ D. Gordon,¹ J. Anderson,² M. Strong³ and M. Power.³ ¹Dept. Fisheries and Oceans, Bedford Institute of Oceanography, Dartmouth, Nova Scotia B2Y 4A2, Canada; ²Dept. Fisheries and Oceans, Northwest Atlantic Fisheries Centre, St. John's Newfoundland A1C 5X1, Canada; ³Dept. Fisheries and Oceans, Biological Station, St. Andrews, New Brunswick E5B 2L9, Canada.

Towcam is a bottom-following optical survey system developed by the department of fisheries and oceans at the Bedford Institute of Oceanography in Dartmouth, Nova Scotia. This system is being used for conducting video and photographic surveys of benthic communities and has been routinely deployed from vessels as small as 19.8 m (LOA). This poster shows examples of recent applications of this new survey tool for a number of benthic studies. Field work on scallop beds was conducted in 2002 and 2003 in the Bay of Fundy to assess the feasibility of operating TowCam from a small vessel (CCG J. L. Hart). Whereas there was a great deal of suspended material in the water, the quality of the digital stills was impressive. This technology will allow us to estimate *in-situ* densities of scallops along with size compositions unaltered by the selectivity effects of the scallop drags that we currently use for our surveys. In addition, estimates of size and numbers of

associated species and qualitative information on bottom type can also be obtained from these pictures—data not usually measured when scallop drags are used to survey the area. The Department of Fisheries and Oceans (DFO) and the Geological Survey of Canada, Atlantic (GSCA) are conducting a project to study the spatial utilization of benthic habitat by demersal fish on the Scotian Shelf. Field studies are being conducted at six sites selected using historical groundfish survey data to identify areas with the highest and lowest probability of encountering juvenile haddock. Towcam is a critical tool in the field program and is used off the C.C.G.S. Hudson to collect video and digital still imagery of the seabed along 5-km transects. This video and still imagery along with other data are being analyzed to look at the interrelationships between surface-dwelling benthic invertebrates, fish and seabed habitat characteristics over spatial scales ranging from kilometers down to a few centimeters. Herring eggs adhere to the bottom substrate after spawning takes place. Because of the timing of this survey (August) no herring spawning had yet taken place on German Bank (although there is now substantial reported spawning activity from the fishing fleet over the last few days) and so no herring spawn was observed. We believe that this technology could be very useful in determining the substrate on which spawning occurs and in mapping areas of successful spawning activity. The images captured are sufficient to be able to identify this with ease, but there would be the issue of bottom suitability to safe TowCam operations because much of the spawning area is of highly irregular bottom. The Gulf of Maine Crustacean Fisheries Research Section at St Andrews N.B. has tested Towcam for capturing benthic geo-referenced video footage used to determine lobster distribution and abundance in the shoal waters of Lobster Bay Nova Scotia. A large area could be surveyed in a single day because of the fast towing speed and the large camera footprint rendered when the altitude was between 2 and 3 meters above the bottom. For quantitative purposes, the option of being able to accurately calculate the footprint size at a given time from laser indexing, pitch and roll values and height above bottom was an extremely useful feature.

MOVEMENT OF *ARGOPECTEN PURPURATUS* AND ITS IMPORTANCE FOR MANAGEMENT. Wolfgang B. Stotz and Pablo Araya. Departamento de Biología Marina, Facultad de Ciencias del Mar, Universidad Católica del Norte, Sede Coquimbo, Chile.

The Chilean scallop *Argopecten purpuratus* lives attached by byssal threads to stones or shells on the ground at small sizes. At larger sizes and/or when no stones or shells are available, the scallop constructs a shallow hollow on the ground (a “nest”), the upper shell becoming completely covered by sediment thus the individual completely mimicked with the ground. In this situation the scallop is not easily found by an untrained diver and probably

partially hidden to its main predatory crabs. Considering these characteristics of shelter, it is not suspected that this scallop species exhibits much movement on the ground. Nevertheless accumulations of scallops in shallow waters, probably produced by directional active or passive movements of the individuals, have been observed. These accumulations in shallow waters, connected with storms, can cause the stranding of animals. In fact, in 1999 a mass stranding of about 2 million individuals occurred in the bed of Puerto Aldea, which represented a loss of ca. 20% of the entire population of the scallop bed protected and managed by fishers of this village. In order to avoid these losses and to improve the management strategy, the movement of the scallop within the bed was studied. To get an idea of movement intensities within the bed and its eventual directionality, a series of traps were distributed over the area. The traps registered numbers of scallops that moved over a period of time and the direction of their movement. Additionally, with a set of experiments, the influence of the density of scallops in the bed on their movement behavior was studied. Therefore quadrants with different densities of marked individuals were installed and the distance and direction of scallop movement registered. Also the abundance of predators and the losses of scallops caused by predation were registered in these experiments. Only in some sites of the bed the traps registered movement, with no clear predominant direction. These observations suggest that movement occurs actively and is not caused by prevailing bottom currents. The movement was most intense when the density of scallops was high. Coincidentally, with higher densities also higher losses due to predation were registered. The results in general suggest that movement is normally caused by escape reactions to predators. When scallop density gets high, predators find their prey more easily. In this situation also, most scallops when escaping from the predator disturb other scallop individuals, which in turn move, abandoning the shelter of their nest thus becoming more susceptible to predation. Considering these movements of the scallop and its causes and consequences, the maintenance of low densities within the bed is suggested as management strategy to protect the scallops from predation and avoid losses. Individuals in areas of high densities of scallops within the bed, produced by occasional intense recruitments, should be moved by divers to scallop free areas thus increasing production of the bed by an increase of occupied bottom area and not by an increase of its density.

DEVELOPMENT OF SUSTAINABLE DIVER-FISHERY FOR *PECTEN MAXIMUS* IN NORWAY. Oivind Strand, Tore Strohmeier and Stein Mortensen. Institute of Marine Research, P.O. Box 1870 Nordnes, N-5817 Bergen, Norway.

The great scallop *Pecten maximus* is distributed along the European Atlantic coasts, north to Lofoten Islands in Norway (69°N). Dredge exploitation of great scallop in Norway has been impeded

by the unfavorable bottom conditions, and scuba diving has been the common harvesting method. A commercial diver-fishery has developed during the last decade, with the main fishing areas west of Trondheim (64°N). The harvest is not regulated, while selling scallops is regulated through licensed dealers. In the beginning of the 1990s this statutory marketing was implemented, and data on catch appeared. Prompted by efforts on developing a shellfish industry the catches increased and has been approximately 400–700 t since 1999, with a value of about 2 million US dollars. In a diver-fishermen team a diver may catch 150–250 kg scallops per day (3–4 scallops per kg), 3–5 days a week. The increase in diver participation in this fishery during 1998 to 2000 incited the Norwegian Labor Inspection Authority to set new requirements on diver certification for scallop harvesters. This reduced the number of diver-fishermen and contributed to regulate the fishing effort. In recent years there are some indications of lower availability of large scallops (>12 cm shell height) and new scallop beds are exploited northward from the main fishing areas. Because the fishery developed the possibility of over-exploitation of the harvestable stock this has been an issue, also among many harvesters. Management of the scallop fishery has also been associated with the development of scallop sea ranching and possibilities of stock enhancement. In 2004 a new law was implemented, regulating stock enhancement through release of cultured sedentary species as mollusks, crustaceans or echinoderms. This law assign the ownership of released scallops within a licensed area. In 2005 the Fishery and Aquaculture Industry Research Fund and Institute of Marine Research initiate a pre-project, involving the diver fishermen, to propose current research priorities and management strategies for a future sustainable scallop diver-fishery.

PREDATION ON HATCHERY REARED SCALLOP SPAT (*PECTEN MAXIMUS* L.) BY THE BALLAN WRASSE (*LABRUS BERGYLTA*) IN CONTROLLED EXPERIMENTS AND IN SEA RANCHING. Tore Strohmeier,¹ Guri G. Oppegård² and Oivind Strand.¹ ¹Institute of Marine Research, Norway; ²University of Bergen, Norway.

Sea ranching of scallops (*Pecten maximus*) in Norway has been associated with great losses caused by predation by the edible crab (*Cancer pagurus*). This predation is now hindered by the development of a fence that prevents intrusions of crabs, which has resulted in high survival of scallops in sea ranching. Because crab predation is radically reduced, the opportunity of seeding scallops directly from hatchery to bottom culture emerged. A straightaway release of scallops from hatchery will greatly reduce the labor effort and cost associated with operation of intermediate culture. In the summer of 2002 Helland Skjell AS carried out preliminary experiments with early transfer of spat from intermediate culture to bottom culture. The seeding of scallops from intermediate culture

attracted fish and by seeding 30-mm spat it was observed that the ballan wrasse (*Labrus bergylta*) nab on the scallops. Tank and field experiments were conducted to test if ballan wrasses predate on hatchery reared scallop spat. Ballan wrasses were offered spat from 15 to 35 mm in shell height. Predation was recorded in 20 of 40 tanks and predation was greater than 20% in seven tanks. In these seven tanks the mean predation frequencies significantly decreased with increasing shell height. Predation was not recorded for spat larger than 30 mm in shell height. There was also indication of size dependent predation from the field experiment, but other fishes than ballan wrasse may be the predator.

SPATIAL AND TEMPORAL DISTRIBUTION OF SEA SCALLOP, *PLACOPECTEN MAGELLANICUS* IN THE BAIE DES CHALEURS, QUEBEC, CANADA. Benoît Thomas,¹ Michel Giguère² and Sylvie Brulotte.² ¹Min. Agr. Pêch. Alim., CAMGR, C.P. 340, Grande-Rivière (Québec), G0C 1V0, Canada; ²Department of Fisheries and Oceans, IML, C.P. 1000, Mont-Joli (Québec), G5H 3Z4, Canada.

The first studies regarding sea scallop spat collecting activities in Gaspésie were done by the private sector in the mid 1980s and by universities in early 1990s in a small part of the peninsula. Between 1999 and 2001, new activities were realized along the coast from Miguasha to Gaspé. Since 2002, more precise factors were examined in the two most successful sectors. Within the last 2 years, the vertical and temporal distributions of the two scallop species (*Placopecten magellanicus* and *Chlamys islandica*) and other associated organisms were examined. In the two sectors of interest, Bays of Tracadigache and Gaspé, a mean of 1200 to 3400 giant scallops/bag was collected in the best sites. The mean number of scallop spat per bag decreased between the autumn and following summer and could be as high as 80% in Tracadigache. The temporal and vertical distribution patterns changed with sector and year so it is still difficult to distinguish a pattern and further analyzes, and trials may be needed in the future. The two sectors are describe as their quality to minimize biofouling and other non productive by catch.

AGE COMPOSITION AND GROWTH RATES OF QUEEN SCALLOPS *AEQUIPECTEN OPERCULARIS* (L.) AROUND THE ISLE OF MAN. Belinda J. Vause, Bryce D. Beukers-Stewart and Andrew R. Brand. Port Erin Marine Laboratory, University of Liverpool, Port Erin, Isle of Man, IM9 6JA, British Isles.

Landings of the queen scallop *Aequipecten opercularis* (L.) have fluctuated widely around the Isle of Man since the fishery began in 1969. These fluctuations have been attributed to large variability in recruitment. Regardless it remains the second most

valuable species accounting for nearly 30% of all fish and shellfish landings in 2002. There are no regulations on the fishery, however, it predominantly operates between June and October (the closed season for the great scallop *Pecten maximus* L.) and it is not economically viable to land individuals less than 55 mm in shell height. Stock abundance has been well monitored with fisheries independent stock surveys since 1992, but the age structure and growth rates of the populations have received little attention. The aim of this study is 2-fold. Firstly, to ascertain the best method of age determination and secondly to investigate seasonal and spatial variation in age composition and growth rates of the exploited queen scallops around the Isle of Man. Three methods of determining age composition were used and compared: reading of the annual growth rings from untreated shells, reading of the annual growth rings from treated shells and length frequency analysis. A sample of 150 queen scallops were collected during stock surveys in June and October 2004 from 3 fishing grounds; South PSM, East Douglas and Laxey. An additional sample of 500 queen scallops were collected from South PSM and kept alive in the aquarium. Queen scallops can be difficult to age as their annual growth bands are not always clear. A sub-sample of 150 of the live sample were tagged and aged to the best of our ability in their original state. These animals were then sacrificed and their shells were treated in order to make the annual growth rings more visible. The left (upper) valve was cleaned of epifauna and epiphytes, treated with 5% NaOCl, washed with 98% ethanol, rinsed with water then dried at 60°C for 12 hours. These individuals were then aged again and the results compared to determine if this treatment assisted in the ageing procedure. The remainder of the live samples are being kept in the aquarium for 12 months to validate the formation of an annual growth ring. The 6 frozen samples were treated as earlier mentioned, measured and aged. Ageing the scallops was conducted by three independent readers, before and after treatment, and size was recorded as shell height (mm). Length frequency analysis was conducted using Bhattacharya method on the size data to mathematically determine age composition. The results from these three methods of age determination were compared. It was more difficult and less precise to determine the age of queen scallops before treatment compared to after treatment. An average of 84% (SE 4.6) of untreated shells were considered to be readable by the three readers as opposed to nearly 100% after treatment. In addition, differences between the readers decreased after treatment (precision index before treatment 29.7, after treatment 23.6). A significant difference was found between the ages determined before and after treatment (Kolmogorov-Smirnov test $Z = -4.206$, $P < 0.001$) and regression analysis showed that ageing before treatment was biased towards the lower ages ($y = 0.77 + 0.54$). Further results will be presented comparing length frequency analysis with these results. The age distribution at South PSM was relatively even for the first 3 cohorts with approximately 20%; 1-year olds, 30%; 2-year olds, 30%; 3-years olds, then de-

creasing to 13%; 4-year olds 6%; 5-year olds, as would be expected with natural and fishing mortality. East Douglas also had individuals present in each year class but 3- and 4-year olds were most abundant. At these two grounds there was little seasonal variation in the age compositions of the populations. The age composition at Laxey was dominated by 1-year olds that accounted for 64% in June and 94% in October. In 2003 there was exceptionally high recruitment-population at Laxey, which has survived to produce this strong year class: recruitment at Laxey, prior to this, was poor. Von Bertalanffy growth curves were fitted to the treated shell data, and mean size at age was calculated to investigate seasonal, temporal and spatial variation in growth. Generally mean size at age increased between June and October for 1-, 2- and 3-year olds but not 4- and 5-year olds and at this point the growth curves plateaued. This was expected because most growth takes place over the summer period and growth slows down considerably with age. The difference between mean size of 1-year olds in June and October was 8.3 mm at South PSM, 3.2 mm at East Douglas and 13.6 mm at Laxey. Spatial variation between the three grounds was apparent. In June, Laxey had the smallest 1-year olds of the three grounds, yet the largest 3- and 4-year olds. In contrast, East Douglas had the largest 1-year olds but the smallest 3–5-year olds and South PSM was in between. Despite spatial variation of the size of 1-year olds, the growth curves on the three different grounds intercepted at 2 years old, which is when individuals are approximately 55 mm. Despite the time taken to prepare shells we recommend this method over using live specimens because of the improvements in readability, precision and potentially accuracy (see laboratory experiment). If length frequency analysis is found to give comparable results to prepared shells however, this would be a much more cost effective method because these data can be collected quickly and easily in the field. Differences between the queen scallop age compositions on the different grounds seem to be the product of both variable recruitment and the effects of fishing. Several years of poor recruitment at Laxey has resulted in very low abundances of 2-year olds and older. The increase of 1-year olds in the age composition between June and October may be explained by the increase in size due to summer growth and thus the increase in catch efficiency. Analysis of fishing effort on all grounds around the Isle of Man (from a voluntary logbook scheme) shows that for the season of 2003 Laxey incurred 0%, South PSM 15% and East Douglas 33% of total effort. There was no fishing at Laxey because poor recruitment in previous years resulted in a low abundance of economically viable sized queens. This lack of fishing disturbance may explain the fast growth of these 1-year olds at Laxey, whilst East Douglas had the highest fishing effort and the slowest growing 1-year olds. Fishing pressure may also explain the size distribution of the older cohorts. Fishing gear is selective towards larger individuals so higher effort may drive down mean size at age once a cohort is available to the fishery. This increased knowledge of population dy-

namics and monitoring methods will be used to provide management advice aimed at ensuring the sustainability of the fishery.

SCALLOP INDUSTRY IN QUEENSLAND—CHANGES AND OPPORTUNITIES. Lew Williams. Assessment & Monitoring Unit, QDPI&F, GPO Box 46, Brisbane Qld Australia, 4001.

In the Queensland scallop industry, based on (*Amusium japonicum balloti*), scallops are primarily harvested by the otter trawl fleet specifically targeting scallop. Lesser amounts of scallop are taken as incidental catch when trawlers target prawn. The scallop year referred to here is from July to June because this allows better description of the changes in annual scallop harvest. Harvest of scallop meat varied between 400 t and 1700 t from 1988/1989 to 2003/2004. The two lowest harvest years occurred in the last 2 years of the series. The number of boats reporting harvest of scallops each year also declined from approximately 300 boats to about 200 boats. At the same time, mean daily harvest per boat for the last 2 years was only slightly lower than the overall mean daily harvest rate. Two major management interventions have been applied to the otter trawl fishery in recent years with flow-on effects to the scallop sector of the fishery. Firstly, otter trawlers now are effectively managed by a “nights fished” quota as well as by other inefficiencies such as time and area closures including some specifically targeted at the scallop sector. In addition, TEDs have been compulsorily introduced into otter trawl nets, which have changed the dynamics of the scallop sector through, for example, the loss of Moreton Bay Bugs as incidental catch making targeted scallop harvest less profitable in some areas. Secondly, known key scallop producing areas have been closed to trawling since 1997 to allow build up of scallop stocks. These strategies have now changed to include a 2-year harvest rotation and changes in size of the areas involved. These management changes have caused changes in the behavior of fishers, because they seek to maximize daily income while taking into account their view of the riskiness of generating that daily income. There is no simple explanation for this dramatic change in the performance of the scallop sector. Some suggest it is the result of the introduction of the otter trawl management plan in 2000, others suggest that it is the effect of specific management measures for the scallop sector; whereas others suggest that there may have been a weather effect due to drought in the adjacent land mass. There has been a flow-on effect into the processing sector (saucer scallops are shucked by hand) especially from Yeppoon to Urangan. The low production in the last couple of years and the change in fishing patterns of the trawlers has caused considerable rationalization in the processing sector with the number of firms available to process scallops declining substantially. These changes have the short term potential to limit the capacity of the

industry to process high levels of harvest when they occur again. Queensland scallop fishery overview available: <http://www.dpi.qld.gov.au/fishweb/12545.html#5>.

REPRODUCTIVE ECOLOGY OF THE SCALLOP *PECTEN NOVAEZELANDIAE*. James R. Williams¹ and Russell C. Babcock.² ¹Leigh Marine Laboratory, University of Auckland, PO Box 349, Warkworth, New Zealand; ²CSIRO Marine Research, Private Bag No. 5, Wembley 6913, WA, Australia.

Key factors influencing the reproductive success of the scallop *Pecten novaezelandiae* were examined in the Hauraki Gulf, North Island, New Zealand using a combination of field and laboratory studies. Size at maturity was objectively estimated to be 65 mm shell height, although small differences in size at maturity among sites may exist owing to differences in environmental conditions that affect growth rates. Reproductive activity was monitored at four sites from 2000 to 2003 using multiple techniques. Gonad indices appropriate for measuring reproduction were assessed and a method that directly scaled gonad mass to shell height was applied. A visual grading index based on gonad appearance was significantly correlated with quantitative histological and gonad mass data ($r^2 = 0.74\text{--}0.87$). Visual grading facilitated rapid assessment of reproductive condition and could be conducted non-destructively. Repeated observations of visual grade in tagged scallops tethered to the seabed were made *in situ*, the first time that long-term sequential reproductive activity of individuals has been described for a mobile free-spawning animal. Scallops exhibited episodic spawning from spring through to early winter. Temporal variability in gonad size and condition was the result of multiple (serial) spawnings per year. Four to 75% of individuals spawned synchronously between sampling dates. Partial spawnings were common and gonads redeveloped between spawnings. Partial spawning may be part of a bet-hedging strategy to manage the risk of fertilization failure in asynchronously spawning populations. The timing of spawning varied among sites and years, but they often coincided with a sharp drop in sea surface temperature. Scallop spawning behavior reflected their fertilization requirements, releasing millions of gametes in a series of contractions over a short period of time. *In vitro* fertilization success was primarily dependent on sperm concentration, but was also influenced by gamete age and sperm-egg contact time. Maximum fertilization rates (up to 92%) occurred only at high sperm concentrations ($10^6\text{--}10^7$ sperm mL^{-1}). A polyspermy-adjusted fertilization kinetics model explained 87% of the variation in fertilization success. *Pecten novaezelandiae* gamete traits seem to be adapted to fertilization at high sperm concentration. Consequently, low-density populations may be susceptible to allee effects and reproductive failure.

INDEX OF PAPERS PUBLISHED IN THE JOURNAL OF SHELLFISH RESEARCH VOLUMES 18–24 (1999–2005)

1. (1999) Abstracts of technical papers presented at the 19th annual meeting of the Milford Aquaculture Seminar, Milford, Connecticut, February 27–March 1, 1999. **18(1):259–280**
2. (1999) Abstracts of technical papers presented at the 91st annual meeting of the National Shellfisheries Association, Halifax, Nova Scotia, Canada, April 18–22, 1999. **18(1):281–335**.
3. (1999) Abstracts of technical papers presented at the Sixth International Littorinid Symposium, July 2, 1999, Priory, Jamaica, W.I. **18(2):687–700**.
4. (1999) Abstracts of technical papers presented at International Conference on Shellfish Restoration, September 29–October 2, 1999, Cork, Ireland. **18(2):701–729**.
5. (2000) Abstracts of papers presented at the 4th International Abalone Symposium, February, 2000. **19(1):493–542**.
6. (2000) Abstracts of papers presented at the NAFO-ICES-PICES Symposium on Pandalid Shrimp Fisheries "Science and Management at the Millenium," Halifax, Nova Scotia, September 8–10, 1999. **19(1): 543–562**.
7. (2000) Abstracts of technical papers presented at the 20th annual meeting, Milford Aquaculture Seminar, Milford, Connecticut, February, 2000. **19(1):563–584**.
8. (2000) Abstracts of technical papers presented at the 92nd Annual Meeting, NSA, Seattle, Washington, March 19–23, 2000. **19(1):585–668**.

ADDENDUM TO: DIOXIN AND HEAVY-METAL CONTAMINATION OF SHELLFISH AND SEDIMENTS IN ST. LOUIS BAY, MISSISSIPPI AND ADJACENT MARINE WATERS

**RALPH ELSTON, EDWIN W. CAKE, JR., KAREN HUMPHREY, WAYNE C. ISPHORDING,
ROD O'CONNOR AND J. E. (JACK) RENSEL**

[Article in *Journal of Shellfish Research*, Vol. 24, No. 4, 1253–1255, 2005.]

Regretfully, following submission of correct page proofs by authors, an error occurred during the final publishing process in the first column of page 1255.

The 2nd line of the left hand column on page 1255 should read “adjacent waters of Mississippi Sound are, on average, about 10%”.

The Publisher greatly regrets the error.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the Editor or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans*, or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual*, distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").

- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.
- Resolution: *line shots*: 1000 dpi; *halftones/grayscale*: 300 dpi if no lettering, 500 dpi if figure contains lettering.
- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements as B/W, above. Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations*, available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

Page Charges: Authors or their institutions will be charged \$100.00 per printed page. All page charges are subject to change without notice. A handling fee of \$60 will be charged for all manuscripts accepted for publication.

Proofs: Page proofs are sent to the corresponding author and must be corrected and returned within seven days. Alterations other than corrections of printer's errors may be charged to the author(s).

Reprints: Reprints and PDF files of published papers are available at cost to the authors. Information regarding ordering will be available from The Sheridan Press at the time of printing.

Cover Photographs: Appropriate photographs may be submitted for consideration for use on the cover of the *Journal of Shellfish Research*. Black and white photographs and color illustrations will be considered.

Corresponding: Three (3) copies and electronic copy of each manuscript submitted for publication consideration should be sent to the Editor, Dr. Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, 1080 Shennecossett Rd., Groton, CT 06340. E-mail: sandra.shumway@uconn.edu or sandrashumway@hotmail.com

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

- Sponsors an annual scientific conference.
- Publishes the peer-reviewed *Journal of Shellfish Research*.
- Produces a Quarterly Newsletter.
- Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

- You will meet kindred scientists, managers and industry officials at annual meetings.
- You will get peer review through presentation of papers at the annual meeting.
- If you are young, you will benefit from the experience of your elders.
- If you are an elder, you will be rejuvenated by the fresh ideas of youth.
- If you are a student, you will make useful contacts for your job search.
- If you are a potential employer, you will meet promising young people.
- You will receive a scientific journal containing important research articles.
- You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

- Fill out and mail a copy of the application blank below. The dues are 85 US \$ per year (\$45 for students) and that includes the *Journal* and the Newsletter!

REPRODUCTIVE PATTERNS AND THEIR INFLUENCE ON THE POPULATION GENETICS OF SYMPATRIC SPECIES OF THE GENUS *CREPIDULA* (GASTROPODA: CALYPTRAEIDAE)

ALFONSO J. SCHMIDT, JORGE E. TORO¹* AND OSCAR R. CHAPARRO

Instituto de Biología Marina, Dr. J.E. Winter, Universidad Austral de Chile, Casilla 567, Valdivia, Chile

ABSTRACT *Crepidula dilatata* (Lamarck, 1822) and *Crepidula fecunda* (Gallardo, 1979) are sympatric species in southern Chile. Separating them by species is difficult because they are morphologically similar; an important character, which separates them is their comparative larval development. *C. dilatata* includes nutritive eggs within its egg capsules that are consumed by larvae in the capsule during their intracapsular development. Metamorphosis occurs in the capsule, followed by the hatching of crawling juveniles. The *C. fecunda* intracapsular development leads to the release of planktotrophic veliger larvae that persist in the water column for about 15 days prior to settlement and metamorphosis. These two contrasting reproductive strategies (direct and indirect development) may influence the capabilities of these species for dispersal, which could influence their comparative gene flow and population genetics. Newly developing molecular genetic techniques, such as RAPD used in the present study, were useful in identification of the two species studied and provided some initial data on their comparative population genetics. Greater gene flow and interpopulational gene diversity were found in *C. fecunda* (pelagic larva) compared with *C. dilatata* (direct development), with the latter showing populations to be the more genetically heterogeneous within the geographic range studied. It was thus evident that the pattern of larval development (direct or planktonic) influenced the comparative population genetic structure between these two species.

KEY WORDS: *Crepidula dilatata*, *C. fecunda*, Chiloé Island, reproductive patterns, RAPD, population genetic

INTRODUCTION

The basic patterns in reproductive strategies of marine benthic invertebrates include holobenthic cycles, with (a) direct larval development and no pelagic larval phase; (b) completely pelagic cycles and (c) pelagic-benthic cycles where larval development is mixed. The latter case includes the presence of a free-living larva in the water column prior to settlement and metamorphosis in the benthos (Thorson 1950, Mileikovsky 1971, Gallardo 1987, Gallardo 1989).

The presence of a pelagic larva may influence the characteristics of population structure, based on the impact of these stages on the capacity for dispersion of these species (gene flow) (Hunt 1993, Williams & Benzie 1993, Ayre et al. 1997, Hoskin 1997, Kyle & Boulding 2000, Collin 2001, Collin 2003, Nishikawa et al. 2003, Goffredo et al. 2004). A pelagic larva (lecithotrophic or planktotrophic), can remain in the water column for weeks, thus favoring its dispersion, in contrast with the direct mode of development where the individuals hatch from maternal incubatory structures as crawling juveniles (Collin 2001) thus remaining close to their sites of generation. Loss of the larval pelagic phase may favor evolutionary divergence in congeneric species with locally adapted populations; these could diversify in the expression of certain traits in their life histories, reflected in their gene frequencies (Strathmann 1980, Gallardo 1989, Pechenik 1999, Marshall & Keough 2003).

On the other hand, the reproductive strategy, which includes a pelagic larva would guarantee, in the absence of geographic barriers or restrictive oceanic currents, greater larval dispersal and thus greater gene flow. This might however diminish variability in the population structure (Strathmann 1986, Hunt 1993, Palumbi, 1994, Kyle & Boulding 2000, Collin 2001, Hellberg et al. 2002, Whalan et al. 2005), resulting in genetically homogeneous populations.

Species in the Family Calyptraeidae ("slipper limpets") are

typically protandric hermaphrodites. They deposit egg capsules and exercise parental brooding as part of their reproductive strategies. *Crepidula dilatata* (Lamarck 1822) and *Crepidula fecunda* (Gallardo 1979) coexist along a portion of the Chilean coast, having a distribution from 29°58'S to 41°52'S and 12°5'S to 41°31'S, respectively (Collin 2003); both species inhabit both intertidal and subtidal rocky substrates (Gallardo 1977). They can occur at high densities in estuaries and bays along the interior coast of the Island of Chiloé, as well as in protected bays and fjords in the southern channel region of Chile. The species closely resemble each other morphologically, and are best identified based on type of development undergone by their larvae, and secondarily by the maximum size of the adults (Gallardo 1976, 1977, 1979, Brown & Olivares 1996).

Taxonomic studies of the Chilean species of the genus *Crepidula* have been based historically on morphological criteria, where comparisons are made between morphometries of the shell and radula (Gallardo 1979, Brown & Olivares 1996). Also, these species can coexist sympatrically, which makes specific identification even more difficult, particularly when trying to determine the frequency of each species within a given habitat.

Capsules deposited by *C. dilatata* contain nutritive eggs that are consumed as extraembryonic nutrition by larvae developing in the capsules. This factor allows well developed crawling juveniles to hatch from the capsules, having shell lengths of between 0.9 and 1.2 mm (Gallardo 1976, 1977, 1979, Chaparro & Paschke 1990). With *C. fecunda* all the eggs deposited in the capsules develop into veliger larvae that hatch into the water column. They assume a planktotrophic life of about 15 days prior to settlement and metamorphosis, at which time they have a shell length of about 0.65 ± 0.028 mm (Chaparro et al. 2005).

Based on the reproductive mechanisms of these two species it was expected that *C. dilatata* would have a comparatively lower degree of dispersion in the absence of a pelagic larva, consequently reducing gene flow among its populations. On the other hand, *C. fecunda* has a wider dispersion because of its freely drifting larvae, the development of which continues in the water column for a period of about two weeks prior to settlement (Chaparro et al.

*Corresponding author. E-mail jtoro@uach.cl

2005). In view of these considerations, the present research was carried out in an attempt to differentiate between these species at the genetic level using the technique of random amplified polymorphic DNA (RAPDs). A comparison was made on the level of dispersion and the degree of influence exercised by the different reproductive strategies of the two species, and their impact on the isolation of populations.

MATERIALS AND METHODS

Population Sampling

About 50 specimens of the *Crepidula* species introduced earlier were collected from mixed populations inhabiting the intertidal and subtidal zones at sites along the interior shore of Chiloé Island in southern Chile. The sites sampled included: Quempillén (41°52'S; 73°46'W), Quemchi (42°08'S; 73°28'W), Dalcahue (42°22'S; 73°39'W), Queilen (42°52'S; 73°28'W), Chaiguao (43°08'S; 73°29'W) and Yaldad (43°08'S; 73°44'W) (Fig. 1).

As a means of corroborating later results obtained with molecular markers, limpets from each site were identified with species by examining the type of the larval development occurring in their associated egg capsules.

For the study of molecular markers, a tissue sample of about

1 g was taken from the foot of each specimen, fixed in 95% EtOH, and stored in Eppendorf tubes at -20°C until processed.

DNA Extraction

Each specimen's DNA was obtained from a subsample of pedal tissue (100–150 mg), which was macerated and digested in lysis-buffer (50 mM Tris-HCL (pH 8.0); 1.0% SDS; 25 mM EDTA) with 200 µg of protease K (Sigma). The samples were incubated at 37°C for 12 h in 1.5 ml Eppendorf tubes; each tube then received 500 µL of a phenol/chloroform/isoamyl alcohol (24:24:1) solution. The mix in each tube was shaken with a vortex mixer for a few seconds and then centrifuged at ×13,000 rpm for 15 min at 5°C. Following this, the supernatant containing the DNA was aspirated, taking care not to touch the intermediate layer. Each supernatant was transferred to a new 1.5 ml (autoclaved) Eppendorf tube. Each extracted DNA sample was resuspended in 200 µL of 95% EtOH and placed in the cold at -18°C for 30 min to precipitate the sample. The EtOH was then removed, leaving the tubes containing the DNA pellet. Concentration and drying of samples was done using a SAVANT DNA model 110 concentrator. Each DNA pellet obtained was resuspended in 200 µL of ultra-distilled water (modified from Toro 1998), and the samples were cleaned with 200 µL of 8M lithium chloride for 3 h at -20°C and then centrifuged at ×10,400 rpm for 30 min at 4°C (Sambrook et al. 2001). The cleanup of the DNA was finalized by eliminating the supernatant and washing the pellet in 70% EtOH. Finally, each pellet was dried for 20 min using the above SAVANT concentrator, resuspended in 200 µL of double-distilled water, and stored at -20°C until amplification.

DNA in the samples was quantified by reading absorbancies at 260 nm in a UV 2120 UV/VIS spectrophotometer. This was carried out following dilution of sample aliquots to 1/20 in distilled water (Sambrook et al. 2001).

DNA Amplification

Of a total of 49 primers, only three (5'-TAGCCCGCTT-3'; 5'-GTGCGTCCTC-3'; 5'-ACGACGTAGG-3' Biosource International) demonstrated polymorphism.

Amplification of the DNA samples was carried out using the polymerase chain reaction (PCR) employing a total mixture of 25 µL in ultrathin (500 µL) PCR tubes (Gordon Technologies). The reaction mixture was prepared using 1 µL of genomic DNA (ca. 50 ng/µL), 2.5 µL of dNTPs (2 mM), 1.75 µL of MgCl₂ (25 mM), 2.5 µL PCR - buffer ×10, 4.5 µL of the primer (10 µM/µL), 1 unidad of *Taq* ADN polimerasa (5 U/µL) (Invitrogen) and 12.55 µL of double-distilled water (modified from Toro et al. 2004).

The mixture was covered by a drop of mineral oil to avoid evaporation and then each of the samples was placed in a thermo-cycler (Amplifon II, Thermolyne Inc.). The program of the thermo-cycler began with generalized denaturation of the DNA at 95°C for 15 sec followed by 36 cycles, which included a partial denaturation at 94°C for 30 sec, an annealing process at 32°C for 30 sec, and finally a duplication period at 72°C for 1 min; after the 36 cycles the amplified product was maintained at 4°C (Toro et al. 2004).

Agarose Gel Electrophoresis

All of the DNA fragments amplified with the primers used were separated in agarose gels (Invitrogen Ultra Pure 1000), at 1.2% in TBE 0.5 × buffer (44.5 mM tris base, 44.5 mM boric acid,

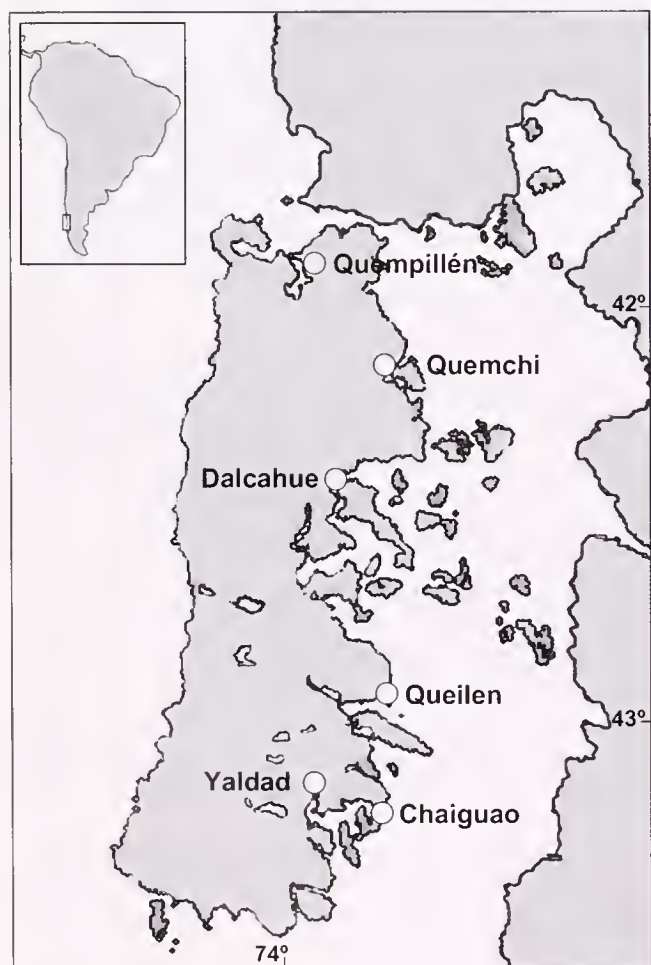

Figure 1. Sampling locations from the eastern coast of Chiloé Island, Southern Chile.

1M EDTA pH 8). Ethidium bromide (10 mg/mL) was added to the gel preparation at a concentration of 1%. Each gel was loaded with a pattern of 1000 bp standard bands (ladder DNA, Promega) for an approximate estimation of the molecular weight of the amplified bands. The gels with the samples incorporated were submerged in an electrophoretic chamber containing TBE 0.5 × buffer (44.5 mM tris base, 44.5 mM boric acid, 1 M EDTA pH 8). Each gel was run at 75 Volts for approximately 1.5 h. Visualization of the band patterns of each gel was done under UV light, and the image of the gel was obtained using a digital camera (modified from Toro 1998).

Data Analysis

The results of the RAPDs, were analyzed based on the band patterns recorded by photography of the agarose gels. Codification was made of the bands present (1) and those that were absent (0), which was then configured into a data matrix.

The identification of species was carried out based on the data obtained in the matrix, searching for bands or patterns of bands particular to each of the two species analyzed.

The statistical analysis was carried out using POPGENE 32 computational programs (Population Genetics Software) (Yeh & Boyle 1997) and the GenAlEx version 5.1 program (Peakall & Smouse 2001).

The gene flow (N_m) was calculated based on the coefficient of populational differentiation (G_{st}) by applying the formula ($N_m = 0.5 (1 - G_{st})/G_{st}$) (Mc. Dermott & Mc Donald 1993). Also determined was the genetic diversity (h), and genetic distance (D) based on the Nei (1978) formula, and also the number and percentages of polymorphic loci. Based on the pattern of genetic differentiation (genetic distance of Nei 1978), a dendrogram was generated, using the unweighted pair group method with arithmetic mean (UPGMA).

An analysis was carried out, by species, of the number of bands present in each of the populations examined, as well as the mean heterozygosity using the GenAlEx program (Peakall & Smouse 2001). An analysis of molecular variance was also carried out

(AMOVA; Excoffier et al. 1992), to evaluate the inter and intra-populational variation, and estimate the degree of panmixia of the populations (Holmes et al. 2004, Sands et al. 2003, Kruse et al. 2003). Use of a Mantel test (GenAlEx program, version 5.1) allowed for making paired comparisons between genetic distances and geographic distances, using a large number of random permutations. The geographic distances between the sampling sites were approximated by measurement from a nautical chart of the coast-line.

RESULTS

The use of the RAPD technique identified 34 loci that were amplified starting with the three primers used.

The patterns of the bands used for each of the species allowed identification of discriminant bands in *Crepidula dilatata* and *Crepidula fecunda* (Fig. 2). The bands existing for *C. fecunda* had weights of about 700, 400 and 300 base pairs. In contrast, *C. dilatata* had bands of only 500 and 300 base pairs. Results from individuals that did not show the presence of discriminant bands were excluded from all analyses because these results may have been caused by technical complications.

Identifications of the samples from all the populations showed that 70% consisted of *C. fecunda* and 19% were *C. dilatata*; 11% of the samples were not identified to species by the molecular method and were eliminated from subsequent analyses (Fig. 3).

The highest percentage of *C. dilatata* occurred at Quempillén, whereas the highest percentages of *C. fecunda* occurred at Dalcahue and Yaldad. The remaining populations (Quemchi, Queilen and Chaiguao) contained both species, with a predominance of *C. fecunda*.

The number of bands amplified for each of the species and each of the populations studied gave an average value slightly lower for *C. dilatata* (22 ± 1.50) than for *C. fecunda* (25 ± 4.67).

At the population level, there was a smaller number of bands recorded for the Quempillén samples, with 18 bands found for *C. fecunda*. The remaining populations maintained equal numbers of bands per species. A few specific bands were identified for indi-

viduals of *C. dilatata* at Quempillén and Quemchi, which were encountered exclusively in limited populations, suggesting a degree of uniqueness of the limited population.

The gene flow estimated for *C. dilatata* was 0.91 and 1.86 for *C. fecunda*. A paired analysis of gene flow estimated between populations showed that for almost all the locations analyzed, the values were greater for *C. fecunda*; exception to this occurred at Quempillén-Queilen and Quempillén-Chaiguao (Fig. 4).

The intra and interpopulational genetic diversity was greater for *C. fecunda* than for *C. dilatata* at each of the locations sampled, with values of 0.20 and 0.14, respectively for the two species (Table 1). The population at Quempillén had lower values for genetic diversity, both for *C. dilatata* (0.09 ± 0.02) and for *C. fecunda* (0.11 ± 0.03).

In *C. dilatata*, the number of polymorphic loci was nearly constant, fluctuating between 19 and 22, whereas for *C. fecunda*, these fluctuated between 16 and 30; the percentage of polymorphic loci for each species was 85.2% and 100%, respectively. The populations that showed the lowest value for polymorphic loci

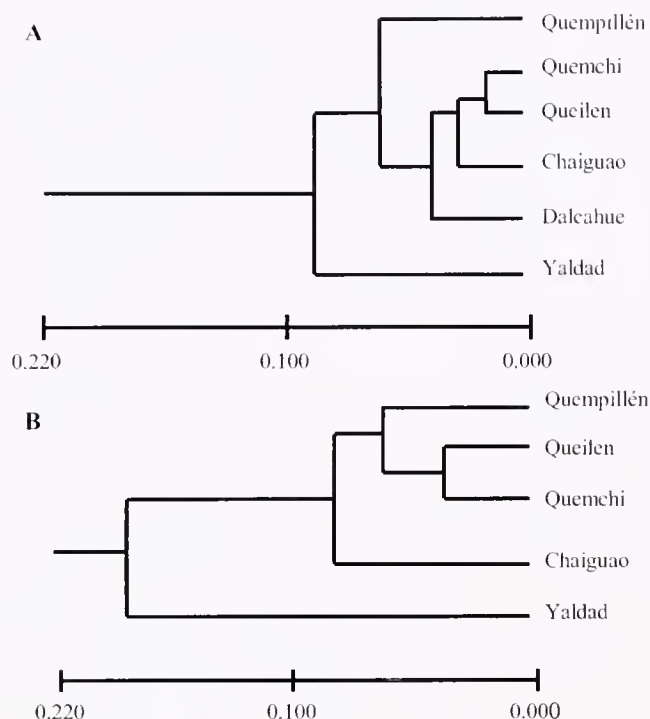

Figure 5. UPGM dendrogram of Nei's genetic distance for (A) *C. fecunda* and (B) *C. dilatata*.

were Chaiguao (19) for *C. dilatata* and Quempillén (16) for *C. fecunda* (Table 1).

For *C. dilatata*, the population at Yaldad was that presenting the greatest genetic distance among all the populations studied, whereas populations at Quempillén, Queilen, Quemchi and Chaiguao showed lower genetic distances. In the case of *C. fecunda*, the populations at Yaldad and Quempillén had the highest values for genetic distance in relation to the other populations studied. The populations at Quemchi, Chaiguao and Dalcabue had lower values for genetic distance, with Dalcabue the most outlayer from the group (Fig. 5, Table 2).

The magnitude of the genetic distance (Nei 1978) for *C. dilatata* was approximately double that for *C. fecunda* (Fig. 5).

The average heterozygosity of each of the populations studied was greater for *C. fecunda* than for *C. dilatata*. In the Quempillén population, *C. dilatata* and *C. fecunda* had lower values than all the other populations studied, suggesting that this location had unusual biological and oceanographic characteristics.

The analysis of molecular variance showed significant differences ($P < 0.01$) between *C. dilatata* and *C. fecunda*, explained by

intrinsic variations in each population. In both species the percentage of interpopulational variation was greater than the intrapopulational variation, indicating that the total genetic variation was, for the most part explained by differences among populations (Table 3).

Correlation between geographic distance and genetic distance, using 5,000 permutations, showed significant correlations ($P < 0.05$) for both species. When the genetic distance was estimated for *C. dilatata* we obtained a Mantel value of -0.081 , whereas the value obtained from the Mantel correlation for *C. fecunda* was 0.260 .

DISCUSSION

The RAPD marker technique permitted identification of discriminant bands, which allowed species discrimination among samples of *Crepidula* spp. as reported for other taxa (Crossland et al. 1993, Andre et al. 1999, Rego et al. 2002, Costa et al. 2004, Liu & Cordes 2004).

The two species were found sympatrically in some of the populations studied. *C. fecunda* was the only species identified from Dalcabue and Yaldad locations (marine conditions), whereas at Quempillén (estuarine conditions) more than 75% of the individuals were *C. dilatata*. This suggested a difference in distribution between the two species based on environmental differences in water mass. The percentage of unidentified individuals (11%), could be because of technical problems encountered during the DNA extraction, as well as in the amplification procedure.

The interpopulational gene flow for *C. dilatata* ($N_m = 0.91$) was less than that for *C. fecunda* ($N_m = 1.86$). Slatkin (1994) indicated that values for this parameter above unity indicated that populations were overcoming the effects of genetic drift, and thus impeding local differentiation.

Paired analyses for populations of the two species, suggested a higher gene flow for *C. fecunda* than for *C. dilatata*. The exceptions that favored the species with direct development (*C. dilatata*) occurred in comparisons between Quempillén and Chaiguao and Quempillén and Queilen. A similar situation has been described for the Chilean oyster *Ostrea chilensis*, where aquaculture activities have distorted the population genetic structure caused by transfer of juveniles from one culture location to another (Toro & Aguila 1996).

The greater degree of gene flow within the populations of *C. dilatata* from Quempillén, Queilen and Chaiguao, could be related to the presence of superficial marine currents (0–30 m), which run from the Gulf of Ancud to the Gulf of Corcovado having a net transport from the north toward the south of Chiloé Island (Silva et al. 1998).

TABLE 3.
Molecular variance (AMOVA) for *C. dilatata* and *C. fecunda* using 999 permutations.

Species	Level	D.f.	Mean Square	% Variance	P	Mode of Development
<i>C. dilatata</i>	Among population	3	14.268	75.5%	<0.01	Direct
	Within population	45	3.365	24.5%		
<i>C. fecunda</i>	Among population	5	41.543	73.9%	<0.01	Planktotrophic
	Within population	171	3.734	26.1%		

This condition could facilitate the drift of juvenile individuals by rafting, as reported for *Crepidula convexa* (Collin 2001).

The greater genetic diversity found for *C. fecunda* in each of the populations studied may be explainable based on its having a pelagic larval stage lasting about two weeks. This amount of time in the waters along the coast of Chiloé would give the larvae of this species ample time for broad dispersion, promoting genetic interchange among populations. The populations of both species at Quempillén showed lower values for genetic diversity, suggesting reduced dispersion, or even larval retention (Bilton et al. 2002). This probability is supported by the hydrographic configuration of the Quempillén estuary, which has natural barriers to the entrance and exit of larvae.

The percentage of polymorphic loci fluctuated between 47.0% and 88.2% for *C. fecunda* and 55.8% to 64.7% for *C. dilatata*. These values were higher than average values for polymorphic loci reported for molluscs (41.2%, Fujio et al. 1983). The percentage of polymorphic loci in the oyster *Ostrea edulis* was between 18.2% and 40.9% (Saavedra et al. 1993), and in the prosobranchs *Cominella lineolata* and *Bedeva hanleyi* it was 24.1% and 41.7% respectively (Hoskin 1997). Based on the preceding, the values presented from the present study are comparatively high, which may be because of the use of DNA based molecular techniques.

The dendrograms for both species show that the genetic distance of *C. fecunda* is half that present in *C. dilatata*. This allows the inference that differences in their reproductive strategies (pelagic larva versus direct development) have an important effect on the genetic structure of the populations of each species. The genetic distances of species with direct development such as *Crepidula cf. convexa* (0.008–0.076) and *Crepidula convexa* (0.037–0.057) (Hoagland 1984) were lower than those presently reported for *C. dilatata* (0.0067–0.2004), which indicates that genetic interchange in the latter species is comparatively less. Greater or lesser genetic interchange may depend on factors such as the population density (Scheltema 1971, Kyle & Boulding 2000), or reproductive variables such as the effective population size (Hedgcock 1994) and presence and duration of the pelagic larval period (Hellberg 1996, Star et al. 2003). *C. convexa* produces from 8–20 capsules per female with each capsule containing 15–25 embryos (Hendler & Franz 1971). *C. dilatata* produces only 9–22 capsules per female with a range of 2–12 embryos per capsule (Penchaszadeh et al. 2002). These factors could strongly affect the dispersive capabilities of these species, because a greater number of descendants per generation would be more conducive to net gene flow between populations.

The genetic distance for *C. fecunda* (0.0131–0.1042) was mildly comparable with *Crepidula fornicata* (0.003–0.016) and *Crepidula plana* (0.052–0.097) (Hoagland 1984), all of which have a larval planktonic phase. The low values for genetic distance in *C. fecunda* could be because of local marine currents whose magnitude and direction of flow (Silva et al. 1998) impeded ef-

fective larval transport among some of the populations studied (Scheltema 1971).

The averages of heterozygosity for *C. dilatata* (0.09–0.16) and for *C. fecunda* (0.11–0.19), were within the ranges reported for different species of molluscs (0.05–0.21, Fujio et al. 1983). The average heterozygosity was low for *C. dilatata*, which indicated that the genetic interchange among its populations was very low, suggesting a future decline in the genetic diversity of the gene pool within these populations. This heterozygosity not only may be influenced by the mechanics of reproduction of the species (e.g., absence of pelagic larvae), but also by geographic and oceanographic factors, which may interrupt the flow of individuals among the populations (Palumbi 1994, Collin 2001, Wares et al. 2001, Hellberg et al. 2002, Zacherl et al. 2003, Whalan et al. 2005).

Species with direct development such as *C. convexa* and *C. atrasolea*, share similar characteristics as those of *C. dilatata* based on the results of the AMOVA. In these cases the interpopulational variation was greater than intrapopulation variation, indicating that the genetic variability was greater among the populations (Hellberg 1996). In contrast, the AMOVA data presently obtained for *C. fecunda* do not coincide with previously reported data for *C. fornicata*, as the latter species shows less interpopulational variation (Collin 2001). *C. fecunda*, releases intermediate-sized larvae having shell lengths of 0.18–0.37 mm (Chaparro et al. 2002), whereas *C. fornicata* larvae are 0.44–0.48 mm in length (Collin 2001). Shell length at settlement in these species are 0.65 ± 0.028 mm (Chaparro et al. 2005) and 0.94–1.00 mm (Pechenik et al. 1996), respectively. As cited earlier *C. fecunda* has a pelagic life of only 15 days, whereas that of *C. fornicata* is 34 days (Thouzeau, 1991). Differences in the pelagic period of the life cycle imply different capabilities for in larval dispersal, which could have an impact on the genetic homogeneity of the populations (Ayre et al. 1997, Nishikawa et al. 2003).

The positive correlation between geographic and genetic distances, but low values for correlation between populations of *C. fecunda* and *C. dilatata* as shown by the Mantel test, may be because of the fact that the greatest distance between populations was only 230 km, which may influence the sensitivity of the analysis (Hellberg 1996, Exadactylos et al. 2003). Also, the physiographic configuration of the coastline may also have effected the low correlation given by the Mantel test (Wares et al. 2001, Hellberg et al. 2002, Zacherl et al. 2003). For example, whereas the populations at Yaldad and Chaiguao are closer geographically (39 km of coastline), their genetic distances are very high (*C. dilatata* = 0.2004; *C. fecunda* = 0.1042). Yaldad is a protected bay, and is not exposed to direct influence from subantarctic, and estuarine water produced eastward of Chiloé island (Silva et al. 1998). The Chaiguao region is more exposed to direct influences of the former water masses, and we suggest there is very low probability of larvae from Chaiguao entering Yaldad Bay.

To summarize, the present study focused molecular genetic

techniques on the specific differentiation between *C. dilatata* and *C. fecunda*. These methods are a valuable complement to classical morphometric methods, particularly when there exists phenotypic plasticity influenced by environmental conditions at each locality (Seed 1992). The results of the present investigation support the hypothesis that the presence of a pelagic stage in the life cycle of a *Crepidula* species is conducive to comparatively greater inter-population gene flow, which in turn produces greater heterozygosity in the populations. In contrast, direct development leads to an increase in intrapopulation homogeneity and isolation in populations because of constraints in dispersion encountered by the juvenile stages.

Continued research along the lines developed in the present study, supported by ecological and oceanographic studies, is of

great interest because it can provide a more detailed vision of the factors affecting the population genetics of *C. dilatata* and *C. fecunda*. This study is of particular interest in the marine environment because it is not only an interesting, well defined model within a limited geographic area, but it can also serve as a general model of population genetic processes of systematic and evolutionary import by combining classical and newly molecular genetic methods.

ACKNOWLEDGMENTS

The authors thank Ms. J. Ojeda and Ms. M. Montoya for their help with the lab analysis. The work was supported by the Fondocyt-Chile research grant 1020171.

ABSTRACT Among the *Thais* species, the broad consensus has long been that *Thais clavigera* (Kuster) is the most noxious predator of cultured oysters in Taiwan. Recently, two new *Thais* species (i.e., *T. rufotincta* Tan & Sigurdsson 1996 and *T. keluo* Tan & Liu 2001) have been identified and named in Taiwanese waters yet their impact on oyster culture is unknown. In this study, the overall impact of the three species on the oyster industry was estimated on the basis of their distribution in the field, their feeding rate and their temperature preference based on laboratory tests. The proportion of *T. clavigera* varied monthly from 24% to 100%, whereas the percentage of *T. keluo* was negatively correlated with low tide levels ($P < 0.01$). *Thais clavigera* occurred widely in the intertidal zone and *T. keluo* and *T. rufotincta* near the subtidal, this distribution pattern was consistent with their specific-preferred temperatures in the upper-limits. As shown in the laboratory, *T. clavigera*, *T. rufotincta* and *T. keluo* preferred 36°C, 32°C and 30°C water, respectively. In the field, the respective average feeding rate of *T. clavigera*, *T. rufotincta* and *T. keluo* was significantly different at 0.054, 0.010 and 0.038 oysters snail⁻¹ day⁻¹ ($P < 0.05$). Based on the abundance of the three *Thais* species at oyster cultural sites (Liu 2002) and their feeding rates, when oyster predation was made up of *T. clavigera*, *T. rufotincta* and *T. keluo*, predation was respectively 87%, 11% and 2%. The most destructive *Thais* species in the oyster industry remains *T. clavigera*, and it accounts for 87% to 100% of all intertidal losses in Taiwan. To the other one-third subtidal culture industry, owing to the use of off-bottom raft or longline method, the distribution of snails extended to subtidal may be limited and the reported major predator is the flatworm of *Stylochus orientalis*.

KEY WORDS: *Thais clavigera*, *Thais rufotincta*, *Thais keluo*, temperature preference, distribution, Taiwan

INTRODUCTION

Thais clavigera (Küster) is a common predator in intertidal rocky shores of East Asia, feeding on barnacles, chitons, gastropods, bivalves and polychaetes (Taylor & Morton 1996). It is also a major predator to oyster culture, which is responsible for an annual reduction of up to 10% to 50% of the oyster industry in Taiwan (Lin & Hsu 1979). According to the records of the Taiwan Fisheries Bureau, oyster cultural areas covered 10,700 hectares, and total production was 10,400 metric tons in 2003 (Taiwan Fisheries Bureau 2004). Although oyster predators (i.e., snails of *T. clavigera*, *Cymatium pileare* [Linnaeus] and *Siphonalia fusoides* [Reeve], crabs of *Scylla serrata* [Forsk.] and *Matuta inanis* [Forsk.], flatworm of *Stylochus orientalis* Bock and fish of *Therapon jarbua* [Forsk.]) have been documented, the prominent two are *T. clavigera* and *S. orientalis* (Kuo 1964, Lin & Tang 1980). Between the two, *S. orientalis* is the major predator in subtidal culture, causing up to 50% of the economic loss (Lin & Tang 1980). On the contrary, *T. clavigera* is the predominant predator intertidally (Kuo et al. 1998).

In light of such predatory behavior, the great economic and ecological significance of the snail *T. clavigera* cannot be denied. However, the situation may have become more complicated because two new *Thais* species have recently been identified, (i.e., *T. rufotincta* [Tan & Sigurdsson 1996], and *T. keluo* [Tan & Liu 2001]), and these two newly named species reportedly occur in the same areas as *T. clavigera*. Not until the present study have we gained much insight into their effects on the oyster industry. In the

present study, therefore, the potential impact of these two congeneric *Thais* predators on the oyster industry of Taiwan was evaluated from the perspective of their field distribution, feeding rate and their temperature preference.

MATERIALS AND METHODS

Populations of *Thais* species were collected on a monthly basis from September 2000 to January 2002 at oyster cultural sites (i.e., Chiku and Tungkan) and nonoyster cultural sites (i.e., Tamsui and Taichung) (Fig. 1). In a preliminary survey, it was determined that although these three snails inhabit the same areas, by and large, they typically occur in different zones (i.e., *T. clavigera* is common in the intertidal areas, whereas *T. rufotincta* and *T. keluo* are more prevalent in the lower zones). Thus, the decision was made to collect snails in the zones near the subtidal during the periods of low spring tide. Information concerning the tidal heights on the sampling days was obtained from the Central Weather Bureau, Taiwan (Central Weather Bureau 2000–2003). As for data analyses, the number of each *Thais* species (i.e., *T. clavigera*, *T. rufotincta* and *T. keluo*) was counted, and the percentage of each species from every collection was determined.

Feeding experiments were conducted during the November 2000 to October 2001 period. Thirty to thirty-five snails of a single species with a shell length of 20–30 mm were put into an enclosed cage (30 × 30 × 25 cm; mesh size 1.5 cm), and this was replicated 2–4 times for each species. The cages were hung in the oyster cultural area at Chiku. Cultural oysters (about 70–80 individuals cage⁻¹) with a shell length of 50–60 mm were provided for the snails to feed *ad libitum*, and fresh oysters were replaced monthly. Additionally, cages containing oysters without snails were also

* Corresponding author. E-mail: lilian@mail.nsysu.edu.tw

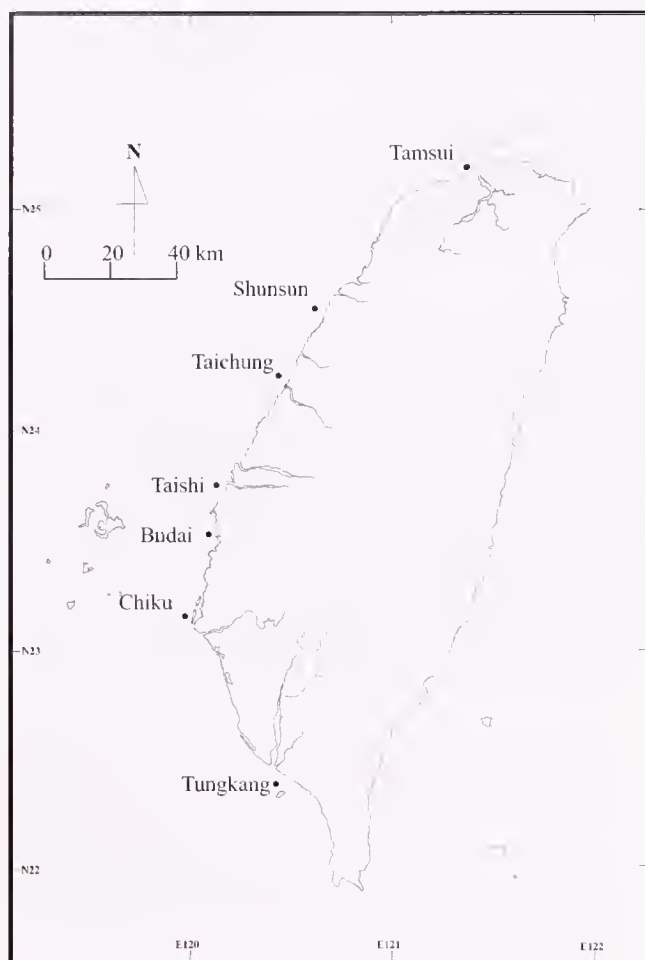

Figure 1. Location map showing the various study sites of the *Thais* species.

supplied as control groups. The number of eaten oysters per snail, the shell lengths and the total wet weights of the snails were calculated to determine the feeding and growth rates.

For the experiments on temperature preference, snails were collected in the zones near the subtidal on the days of low spring tides in July and August 2003 and were kept moist during transportation. For comparative purposes, the collection site Shunsun (Fig. 1), which had enough specimens of the three *Thais* species was sampled. Upon arrival at the laboratory, the snails were kept in their shipping containers until experimental use. The total shipping and handling time prior to the experimental analyses was, at most, 6 h.

A thermo-preferendum chamber was installed horizontally with a 7.14-m long transparent plastic pipe with an inner 11-cm diameter and a 0.5-cm thick wall (Chen & Chen 1991). The pipe was closed at both ends. Two stainless-steel tubes (an outer diameter of 2.1 cm and a wall thickness of 0.05 cm) were placed in the upper one-fifth of the plastic pipe, and these served as heat exchangers. Chilled water was passed through one of the tubes in one direction, whereas heated water was passed through the other in the reverse direction, thereby forming a recirculating countercurrent heat-exchange system. An aeration tube, fitted with a stainless-steel rod to prevent flotation, was installed along the bottom of the plastic pipe to increase dissolved oxygen, improve heat exchange and prevent vertical stratification. On the upper surface of the plastic pipe, seven holes had been drilled to allow us to measure the temperatures and to release test snails into the pipe. When the system was in operation, a continuous thermal gradient was formed inside the pipe, and it ranged from 16°C at one end to 36°C at the other.

Each experiment began with the release of snails into the test pipe in the regions of the low-, mid and high-temperature openings after the thermal gradient had stabilized. The number of each species used in every experiment was in the range of 51–311 individuals. No food was provided during the trials, and none of

For statistical analyses, the simple linear regression was used to determine if species appearance was dependent on tidal level. Linear regressions together with an ANCOVA were applied for the analyses of snails' feeding and growth data. The χ^2 -test of independence was used to determine whether there were differences in

the 24-h distributions of the thermal preferences of the three *Thais* species.

RESULTS

Although all the *Thais* species were found at each of the collection sites, one of the three species was relatively uncommon (<1% of the total samples; data not shown) at each site. These were *T. rufotincta* at Tamsui and Taichung, *T. keluo* at Chiku and *T. clavigera* at Tungkan. Because of the limited number of samples, a species that was uncommon at a particular site was excluded in the analysis for that site. In Tamsui, the compositions of *T. clavigera* and *T. keluo* varied monthly from 24% to 97% and 3% to 76% of the total (Table 1 & Fig. 2). A positive correlation between the percentage of *T. clavigera* of the total and low tide was found (i.e., $y = 0.43 + 0.936x$; $P < 0.01$), but the percentage of *T. keluo* of the total was negatively correlated with the low tide on the sampling days ($y = 0.568 - 0.932x$; $P < 0.01$). In simple terms, the higher the tide level, the less abundant were *T. keluo*. This pattern was similarly observed in the August to September, 2003 collections from Taichung. However, the correlation was not significant for *T. rufotincta* and *T. clavigera* from Chiku or for *T. keluo* and *T. rufotincta* from Tungkan (Fig. 2).

Turning to the feeding experiments, oysters that remained alive during each experimental period were in the ranges of 11% to 90% in *T. clavigera*, 67% to 98% in *T. rufotincta* and 24% to 88% in *T. keluo*, respectively. No dead oysters were found in the control groups. The average feeding rate of *T. clavigera*, *T. rufotincta* and *T. keluo* was respectively 0.054, 0.010 and 0.038 oysters snail⁻¹ day⁻¹ (Fig. 3). The slowest feeder was *T. rufotincta* ($P < 0.05$), and monthly variations in the feeding rates of all three species were also apparent ($P < 0.05$) (Table 2). The overall growth of *T. clavigera*, *T. rufotincta* and *T. keluo* was found to have varied respectively from an average of 22.5, 25.2 and 25.3 mm to an average of 40.9, 26.6 and 37.0 mm in length (Fig. 4).

Positive correlations between shell length and cultural interval (month) in all *Thais* species were found (i.e., $y = 1.78x + 24.52$; $P < 0.001$) for *T. clavigera*; $y = 0.13x + 24.75$ ($P < 0.001$) for *T. rufotincta*; and $y = 1.29x + 25.83$ ($P < 0.001$) for *T. keluo*. The slopes significantly differed among species, with a descending order of *T. clavigera* > *T. keluo* > *T. rufotincta* ($P < 0.05$). Additionally, average monthly growth rate differed significantly among species, with values of 0.89, 0.07 and 0.64 mm month⁻¹ for *T. clavigera*, *T. rufotincta* and *T. keluo*, respectively ($P < 0.01$).

Figure 3. Seasonal changes in the feeding rate of the *Thais* species during the November 2000 to October 2001 period. The symbols represent the median of the feeding rates; the error bars indicate the range of the feeding rates.

Species	<i>T. clavigera</i>	<i>T. keluo</i>	<i>T. rufotincta</i>
Feeding rate (oysters snail ⁻¹ day ⁻¹)	0.054 A	0.038 B	0.010 C

With respect to the temperature preference of the three *Thais* species, they were significantly different at all of the collection sites ($P < 0.01$, χ^2 -test) except at Chiku, the data for which are not shown because *T. clavigera* was the only available species, making comparisons with other species impossible (Fig. 5). Comparatively speaking, the *Thais* species in areas of low- (16°C to 20°C) to mid-temperatures (24°C to 28°C) were inactive during the 24-h experimental period, but what was particularly evident was the distinct tendency for *T. keluo* and *T. rufotincta* to escape areas with high temperatures. Just as in the collection from Shun-sun, the snails in this experiment aggregated in different locations of the high-temperature area, with *T. clavigera*, *T. rufotincta* and *T. keluo* respectively showing a preference for 36°, 32° and 30°C (Fig. 5C).

In summary, the average feeding rates of the snails ranged from 0.010–0.054 oysters snail⁻¹ day⁻¹, or in descending order, *T. clavigera* > *T. keluo* > *T. rufotincta*. Moreover, their respective preferred temperature differed significantly, with *T. keluo* and *T. rufotincta* exhibiting a clear preference for lower temperatures than *T. clavigera*. Such differences in relation to their distribution were, in essence, also indicative of the correlation between the low tide levels of their habitats and the percentage of species that appeared. However, this pattern was not always observed in samples from all the collection sites.

DISCUSSION

It has been documented that the distribution of intertidal gastropods reflects the thermal resistance and preferred temperatures of individual species (Newell 1979). Whenever a species had been investigated, the same spatial pattern with respect to other species is found (Underwood 1973). In this study, further evidence in support of spatial zonation was also observed in that *T. clavigera* widely occurred in the intertidal zone, whereas *T. keluo* and *T. rufotincta* appeared lower down. Such distribution pattern was consistent with their preferred temperatures in the upper-limits because *T. keluo* and *T. rufotincta* exhibited lower preferred temperatures than did *T. clavigera* (i.e., 30°, 32° and 36°C), respectively. However, in our results, the correlation between tidal level and species appearance was only found for snails from Tamsui and Taichung but not for those from Chiku or Tungkang (Fig. 2). According to the Central Weather Bureau of Taiwan, the annual average tidal range at the sites of

Tamsui, Taichung, Chiku and Tungkang was respectively 220, 390, 120 and 60 cm (Central Weather Bureau 2000–2003). On the level of thermal and desiccation stress, snails that normally inhabit a small tidal range may be less stressful because of their increased exposure to moisture from wave splash, which allows the lower-down species to distribute upwardly (Newell 1979). Possibly, the marked discrepancy of our results reflects the influence of tidal range on the spatial zonation of these snails.

Depending on the salinity and temperature of the water as well as the size of the oysters or snails, it has been reported earlier that the feeding rates of *T. clavigera* measured in the laboratories ranged from 0.018–0.103 oysters snail⁻¹ day⁻¹ (Lin & Hsu 1979). As for the southern oyster drill, *Stramonita haemastoma* (Linnaeus) (Kool 1987) fed on the American oyster *Crassostrea virginica* (Gmelin) ranges from 0.01–0.09 oysters snail⁻¹ day⁻¹ (Brown 1997). Our field feeding data were 0.010–0.054 oysters

snail⁻¹ day⁻¹, in other words, falling well within the range reported in previous study. And, there was a 5-fold difference between the lowest and highest feeding rates of the three species, with *T. clavigera* having the highest followed by *T. keluo* (0.038 oysters snail⁻¹ day⁻¹) and *T. rufotincta* (0.010 oysters snail⁻¹ day⁻¹).

Seasonal variations in the abundance of the three *Thais* species have previously been observed at some major cultural sites investigated: Shunsun, Taishi, Budai and Chiku (Fig. 1) (Liu 2002). Densities of *T. clavigera*, *T. rufotincta* and *T. keluo* were in the ranges of 0–272, 1–317 and 0–34 individuals m⁻², respectively. Among these sites, *T. clavigera* varied in the range of 96% to 100%, 62% to 99%, 64% to 89% and 61% to 99%, respectively. For *T. rufotincta*, it was 0% to 3%, 1% to 38%, 11% to 36% and 1% to 39%, respectively, and for *T. keluo*, it was 0% to 1%, 0%, 0% and 0% to 2%, respectively. Obviously, *T. clavigera* is the most important species simply on the grounds that they always made up more than 60% of the total.

Based on the percent appearance of the three *Thais* species at the intertidal cultural sites and their feeding rates, in the extreme cases of the percent appearance of 61% for *T. clavigera*, 37% for *T. rufotincta* and 2% for *T. keluo*, the impact of oyster predation by *T. clavigera*, *T. rufotincta* and *T. keluo* was 87%, 11% and 2%, respectively. Of course, when *T. clavigera* was the only species, it was responsible for all of the losses. Considering the feeding rate and abundance of the three species, there is no doubt that the most

destructive species to the intertidal oyster industry remains *T. clavigera*. However, intertidal culture is only two-thirds of the whole industry in Taiwan (Kuo et al. 1998).

To the subtidal one-third, *T. rufotincta* and *T. keluo* are the two new potential predators. Formerly, all oysters were cultivated on sandy tidal flats in the western coast of Taiwan and rocks, bamboo or plastic sticks were used to attract oyster spats to settle. Later on, in 1960s, oysters are grown off-bottom by the rack, raft, or longline method and subtidal culture is getting popular (Kuo et al. 1998). Although data on predation by snails in subtidal culture is not available, oyster farmers usually mentioned that the flatworm *S. orientalis* is a serious problem, causing more than 50% of their economic loss (Lin & Tang 1980). Owing to the use of off-bottom raft or longline method, the distribution of snails extends to subtidal may be limited. Consequently, the impact of snail predation on subtidal oyster industry may reduce greatly. However, further field survey on the distribution of these snails in the subtidal is necessary to verify this hypothesis.

ENERGY BUDGET OF CULTURED FEMALE ABALONE *HALIOTIS TUBERCULATA* (L.)

LUS M. LOPEZ¹* AND PAUL TYLER²

¹Facultad de Ciencias Marinas, Universidad Autónoma de Baja California, P.O. Box 453, 22800, Ensenada, B.C., México; ²School of Ocean and Earth Science, University of Southampton / S.O.C. European Way, Southampton, SO14 3ZH, United Kingdom.

ABSTRACT This study evaluates the effects of three diets, at 3 different temperatures (15°, 18° and 22 °C), on the energy budget of one-year-old abalone. The organisms were fed either an experimental diet based on fishmeal, a commercial abalone diet or fresh seaweed as control. The energy budget was estimated by measuring ingestion, egestion, somatic growth, reproductive investment, respiration, excretion and pedal mucus production. All variables were assessed in female abalone of 16.36 ± 0.17 mm length and 0.24 ± 0.03 g dry weight. Animals fed the formulated diets and cultured at 18°C and 22 °C showed better growth than those fed the natural seaweed diet. However, abalone reared at 18°C and fed the formulated diets used 94% of the total energy consumed, with most of this energy allocated to growth, respiration and reproduction. Individuals cultured at 22°C channeled 22% less energy into growth and almost 2.5 times more energy into reproduction than those cultured at 18°C. Hence, diet and temperature were factors that combined to influence growth rates and gonad development in one-year-old *Haliotis tuberculata*.

KEY WORDS: cultured abalone, energy budget, formulated diets, *Haliotis tuberculata*.

INTRODUCTION

The abalone or ormer *Haliotis tuberculata* has been heavily overfished in European waters and considerable interest has therefore arisen in the artificial cultivation of this species (Koike et al. 1979, Hayashi 1980; 1982, Culley 1981, Culley & Peck 1981, La Touche et al. 1993, Mgaya & Mercer 1994, Mgaya & Mercer 1995). Little information is available, however, on energy partitioning in *Haliotis* species (Barkai & Griffiths 1986; 1987; 1988, Donovan & Carefoot 1998, McBride et al. 2001, Gómez-Montes et al. 2002), especially in relation to artificial diets, and data regarding the effect of different macroalgal diets and individuals reared at different temperatures (Emberton 1982, Peck et al. 1987) show variation between the energy ingested and the total energy used.

The study of energy flow in an individual requires an analysis of the partitioning of ingested energy into the major physiological components using the energy budget equation:

$$I - E = Ab - (Pg + Pr + R + U + M)$$

where I is the energy value of the food ingested, E is the energy egested in feces, Ab is the total food ingested minus the total feces egested, Pg is the energy allocated to production of somatic growth, Pr is the energy incorporated into the reproductive investment, R is the energy used for metabolic demands (respiration), U is the energy value of waste materials, such as ammonia excretion, and M is the energy value of pedal mucus production (Peck et al. 1987, Davies & Hatcher 1998).

The aim of this study was to estimate the effect of diet and temperature on the energy budget of artificially reared *H. tuberculata*, at a time when the individuals were 13 months old and sexually mature for the first time.

METHODS

Abalone Rearing

The *H. tuberculata* specimens used in this experiment were selected from a previous growth experiment that ran for seven months (López-Acuña 2000). Three females of 16.36 ± 0.17 mm length and 0.24 ± 0.03 g dry weight were used per replicate.

Abalone were fed 1 of the following 3 diets: an experimental diet prepared with fishmeal (FM) as the main protein source (Table 1 and Table 2); a commercial abalone diet (CO), obtained from Gulf Feeds, Australia, and formulated with casein as the main protein source, though the exact formulation of this diet is not available (Table 2); and a seaweed diet (SW) as control, consisting of a fresh mix of 66% red seaweed, *Palmaria palmata*, and 34% green seaweed, *Ulva lactuca* (Table 2). Three replicates per diet were held in natural seawater in constant temperature baths ($\pm 0.5^\circ\text{C}$) at 15°C, 18°C or 22°C. The experimental groups were fed a known amount of food every afternoon and any uneaten food (solid material) was collected the next morning (12 h). Daily rations related to wet body mass were about 1% for dry formulated diets and 5% for fresh seaweed; the dry weight samples of each trial (15°C, 18°C and 22°C) were measured.

Determination of the Energy Budget Components

Gross energy content of the samples was estimated by combusting three replicates per treatment in a ballistic bomb calorimeter using benzoic acid as the standard.

Absorption (Ab)

Fecal losses were siphoned, placed in a Petri dish, examined under a dissecting microscope to separate any remaining food from solid feces (mucus material) and transferred to a 25-mL centrifuge tube. The samples were then centrifuged at 3000 rpm for 10 min and any excess seawater was dried. Absorption was calculated for each treatment from the total food ingested minus the total feces egested.

Respiration (R)

Respiration was determined from the conversion of oxygen uptake ($\mu\text{l O}_2 \text{ day}^{-1}$) to energy loss. A preliminary experiment determined the volume of seawater to be used and the experiment duration at a set temperature. The individuals used were of a specific size (16.36 ± 0.17 mm and 0.24 ± 0.03 g) and consumed 20% to 40% of the oxygen in no more than two hours. It was difficult to measure oxygen consumption if less than 20% was used, but if more than 40% was consumed the animals were stressed and oxygen consumption was unstable. Organisms were transferred to 1-L respirometer vessels at 15°C, 18°C and 22°C.

Dissolved oxygen content and temperature were measured in respirometer vessels with and without organisms using a polarographic probe connected to a computer (Endeco, pulsed D.O. Sensor Controller).

Ammonia Production (U)

Experimental conditions for ammonia production were the same as those for oxygen consumption. One-liter vessels were filled with seawater and incubated for two hours. Seawater in the incubator tanks was analyzed at the beginning and at the end of each experimental period; three samples from each vessel were used. Total ammonia excretion was calculated as the difference between experimental and blank readings and expressed as $\mu\text{g-atoms N L}^{-1}$ (Solórzano 1969) from a regression obtained from a series of ammonia standards. Finally, to obtain energy loss by ammonia excretion, a coefficient of $68.9 \text{ kcal mol}^{-1}$ was used (Brafeld & Solomon 1972).

Somatic Growth (Pg)

Somatic growth was assessed as the daily gain in dry body weight measured monthly throughout the growth experiment (López-

Acuña 2000). In the last month, and after evaluating the energy budget parameters, samples of abalone from each treatment were weighed, using whole body values for those animals that did not develop a gonad at 15°C with the three diets (FM, CO and SW). Animals that did show gonadal development in the treatments at 18°C and 22°C were dissected and the gonad separated from the rest of the body, so that the energy expended on somatic growth could be determined. The energy gain in somatic growth was assessed by combusting the soft tissue from the individuals from each replicate.

Reproductive Investment (Pr)

In *Haliotis* species the gonad is closely associated with the digestive gland (the gonadal material includes part of the digestive gland). To obtain a more accurate gonad weight, the digestive gland weight was deducted from the total gonad weight for 25 individuals. The energy consumed was determined as calories per day per animal dry weight, based on the number of days taken to reach the ripe stage (120 days for 18°C and 90 days for 22°C). Gonad weight was then multiplied by its energy content.

With the exception of moisture and lipids, proximate analyses of each diet, feces, whole abalone body from each treatment, whole ripe female gonad and mucus were performed according to standard methods (AOAC 1990). Moisture content was determined by weighing samples before and after drying in a freeze dryer for 36 h at -54°C. Ash content was measured using the remaining dried samples by incinerating at 550°C in a muffle furnace for 8 h. Crude protein content was estimated following the total Kjeldhal nitrogen ($\text{N} \times 6.25$) method. Lipid content was determined by a column procedure using methanol-chloroform-water as the eluting solvent (Bligh & Dyer 1959).

Pedal Mucus Production (M)

Pedal mucus production was measured for each experimental trial (FM, CO and SW diets and 15°C, 18°C and 22°C). Each container (400-mL beakers) was cleaned of food and feces, and refilled with UV-filtered seawater. After six hours the animals were removed and each container was rinsed with distilled water to clean off feces and seawater. The mucus from the foot of each abalone was carefully scraped off into the experimental container. The contents of each container were freeze-dried and reweighed to determine the dry weight of each sample.

Statistical Analysis

A two-way ANOVA ($P < 0.05$) was applied to determine significant differences among treatment means to compare the parameters of the energy budget between diets and temperatures, followed by comparisons of the means using the Kruskal-Wallis (K-W) test. All statistics were calculated using the Sigma Stat package (2002).

RESULTS

Ingestion, Egestion and Absorption

The energy contents (cal g^{-1}) of whole abalone body and feces from each treatment and of whole ripe female gonad and mucus are summarized in Table 3.

The amount of food consumed increased with temperature. The values obtained for ingestion of the SW diet (control) were significantly different among temperatures: $25.0 \pm 0.33 \text{ cal day}^{-1}$

TABLE 2.

Proximate composition of the fishmeal (FM), commercial (CO) and seaweed (SW) diets ($n = 3$).

Proximate Composition	Dietary Treatments

* Gross energy was calculated burning samples in a ballistic bomb calorimeter.

animal⁻¹ at 15°C, 33.9 \pm 1.94 cal day⁻¹ animal⁻¹ at 18°C and 45.8 \pm 1.58 cal day⁻¹ animal⁻¹ at 22°C (K-W test, $H = 23.8$, $df = 8$, $P = 0.0025$) (Table 4).

The highest energy intake occurred at 18°C and 22°C with values of 70.8 \pm 1.82 and 75.8 \pm 4.10 cal day⁻¹ animal⁻¹ for the FM and CO diets, respectively (Table 4).

The egestion values varied in all treatments and differences among diets and temperatures were therefore observed (K-W test, $H = 43.1$, $df = 8$, $P = 0.0017$). The lowest mean percentage of egested energy was observed in abalone fed the SW diet, which was affected by temperature. A value of 11.2 \pm 0.62 cal animal⁻¹ day⁻¹ was obtained for abalone fed the CO diet and cultured at 18°C (Table 4).

TABLE 4.

Fishmeal diet (FM), commercial diet (CO) and seaweed diet (SW), at 15, 18 and 22°C of culture. Energy utilized (%) obtained from 100% *Ab* minus *Pg*, *Pr*, *R*, *U* and *M* (based on the energy budget equation: $1 - E = Ab - (Pg + Pr + R + U + M)$).

Those individuals fed the SW diet showed a significant increase in absorption with temperature (K-W test, $H = 30.9$, $df = 8$, $P = 0.002$). Energy absorption in abalone fed the FM and CO diets was low at 15°C but consistent at 18°C and 22°C. At 15°C energy absorption was not significantly different between formulated diets (K-W test, $H = 23.9$, $df = 8$, $P = 0.24$) (Table 4).

Somatic Growth

The energy values of abalone body tissue (minus gonad value) varied among temperatures for the same diet and among diets at the same temperature (Table 3). The lowest value (3652 \pm 30 kcal g⁻¹) corresponded to the SW treatment at 15°C and the highest (4542 \pm 68 kcal g⁻¹) to the CO treatment at 22°C. The energy channeled into somatic growth was calculated by the factors shown in Table 3. Animals fed the formulated diets and grown at 18°C and 22°C (34.4 \pm 1.77–39.4 \pm 2.10 and 25.2 \pm 1.01–31.4 \pm 1.23 cal animal⁻¹ day⁻¹, respectively) invested more energy in somatic growth compared with those fed the SW diet at the same temperatures (11.3 \pm 0.39–17.1 \pm 0.54 cal animal⁻¹ day⁻¹) (Table 4). Furthermore, by the end of the experiment abalone cultured at 18°C and fed the formulated diets expended more energy on growth than those cultured at 22°C with the same diet (Table 4).

Reproductive Investment

To convert the energy expended on reproduction, a mean ovary weight of 5688 \pm 64 cal g⁻¹ was used. Females selected from the 15°C treatment showed an indeterminate gonad stage, demonstrating that there was no reproductive investment. Juveniles fed the SW diet and reared at 18°C and 22°C expended the lowest energy on reproduction (0.7 \pm 0.04 and 0.9 \pm 0.03 cal animal⁻¹ day⁻¹, respectively) (Table 4). When formulated diets were used, the energy expended on reproduction increased to 2.3 \pm 0.09 cal animal⁻¹ day⁻¹ in the FM treatment at 22°C.

Respiration

Metabolic energy loss as a result of respiration was calculated using an oxy-caloric coefficient as follows: 0.00457 cal μ lO₂ with NH₃ end product for protein respiration (Crisp 1984), 0.00469 cal μ lO₂ for lipid respiration and 0.00504 cal μ lO₂ for carbohydrate respiration (Brafield & Solomon 1972, Elliott & Davidson 1975).

Respiration rates for the organisms fed the FM and CO diets were higher than those for abalone fed the SW diet. Although the size of the animals used was the same for each treatment, the energy consumed was higher in animals cultured at 22°C than in those reared at 15°C (Table 4).

Energy expended through respiration differed between the SW and the formulated diets at 15°C (ANOVA, $F_{4,18} = 130.5$, $P < 0.0001$). At temperatures above 15°C, energy used in respiration increased markedly with temperature. When abalone were maintained at 18°C and 22°C and fed the formulated diets, a significant increment in oxygen consumption was detected, with a mean maximum of 18.4 ± 0.5 cal animal⁻¹ day⁻¹ for those cultured at 22°C and fed the CO diet (Table 4).

Ammonia Production

Diet and temperature significantly affected the rates of ammonia excretion (K-W test, $H = 15.7$, $df = 5$, $P \leq 0.001$) (Table 4). Individuals fed the formulated diets excreted more ammonia (up to 1.2 ± 0.03 cal animal⁻¹ day⁻¹) than those fed the SW diet in all the temperature treatments. The results show that ammonia production by abalone fed the SW diet was low and that the excretion rates increased from 0.4 ± 0.01 cal animal⁻¹ day⁻¹ at 15°C to 0.7 ± 0.01 cal animal⁻¹ day⁻¹ at 22°C (Table 4). In general, the rate of ammonia excretion for animals reared at 15°C was 6.06 µg-atoms NH₄ day⁻¹ on average.

Pedal Mucus Production

There were no significant differences in energy content of pedal mucus production among dietary treatments at each experimental temperature (K-W test, $H = 3.53$, $df = 8$, $P = 0.896$). Values were therefore pooled to obtain the energy content of pedal mucus production (2342 ± 57 kcal g⁻¹) to be used in the calculation of the energy budget losses (Table 3). However, a significant effect of temperature on the production of pedal mucus was observed: animals cultured at 18°C and 22°C expended from 0.7 ± 0.02 – 0.9 ± 0.02 cal animal⁻¹ day⁻¹, whereas those reared at 15°C spent an average of 0.5 ± 0.04 cal animal⁻¹ day⁻¹. Pedal mucus production showed significant differences when formulated diets were used (ANOVA, $F_{4,18} = 14.9$, $P < 0.001$) (Table 4).

DISCUSSION

In this study, animals fed the FM diet and cultured at 18°C showed up to $55.7\% \pm 3.0\%$ investment in somatic growth from

Figure 1. *Haliotis tuberculata* cultured at 18°C and fed a fishmeal-based diet (94% total energy used). Energy flow diagram (calories per animal per day) of ingestion (I), egestion (E), absorption (Ab), somatic growth (Pg), reproductive investment (Pr), respiration (R), ammonia excretion (U) and mucus production (M). Mean value ± standard error.

the total energy assimilated (Fig. 1). *Haliotis tuberculata* possesses physiological mechanisms to use energy more efficiently when fed formulated diets and cultured at 18°C than when fed the same diets at 22°C. Peck et al. (1987) reported that the major component of the energy budget was somatic growth (37.5% of total ingestion), and other studies of land-based culture have shown that *H. tuberculata* has maximal growth at temperatures close to 20°C (Shpigel et al. 1996a, Shpigel et al. 1996b).

The daily respiration energy expenditure increased with temperature and diet. Animals fed the formulated diets spent more energy through respiration than those fed seaweed, even at the same temperature. These results show that temperature and diet have an effect on oxygen consumption rates. McBride et al. (2001) also reported that the stress of higher (24°C to 28°C) seawater temperatures increased respiration rates in *H. tuberculata*.

Ammonia excretion is probably influenced by the protein quality of the food offered. Ammonia is assumed to be the dominant end product of protein catabolism in molluscs (Bayne & Newell 1983). When abalone were fed the formulated diets with high protein content (31%) as opposed to the low-protein SW diet (15.5%), ammonia production increased. Therefore, the rates measured may be used to calculate the energy expended by *H. tuberculata* during these experiments and to determine the nitrogen excretion process during the growth stage.

Both respiration and ammonia excretion were affected by temperature and diets. The former was low in abalone fed the SW diet but increased considerably with increasing temperature. The values reported herein are clearly lower than those obtained in other studies using the same species but different diets, culture temperatures and animal sizes: mean energy used by *H. tuberculata*, *H. midae* and *H. kamtschatica* on respiration was 29%, 32% and 59%, respectively and on ammonia excretion, 0.88%, <1% and <1%, respectively, for 50-g abalone (Peck et al. 1987, Barkai & Griffiths 1988, Donovan & Carefoot 1998).

The daily energy expended through mucus production by *H. tuberculata* in this study was from 0.2 ± 0.01 – 0.9 ± 0.02 cal g⁻¹ of the total assimilated energy. Evidence of the influence of temperature on mucus secretion is rare; however, our data show significant effects of temperature on mucus production, with increases at higher temperatures. The same behavior was found for the whelk *Buccinum undatum*, with mean values of 12.4 mg h⁻¹ at 8.2°C, 13.1 mg h⁻¹ at 10.5°C and 19.5 mg h⁻¹ at 15°C (Kideys & Hartnoll 1991).

Peck et al. (1987) found that *H. tuberculata* of 13.7 mm shell length and 0.12 g body dry weight used ~ 2.4 cal day⁻¹ when fed *Ulva lactuca* and cultured at 15°C, with mucus accounting for $\sim 23\%$ of the energy consumed. Davies et al. (1990) found $\sim 23\%$ of consumption was spent on mucus production by *Patella vulgata*. Nevertheless, in this study, animals of the same size fed fresh seaweed and cultured at the same temperature showed an average 3-fold reduction compared with that observed by Peck et al. (1987). These authors demonstrated the important role of mucus in the energy budgets of organisms that use mucus, such as *H. tuberculata*. It is possible that an assessment of the energy used by an individual of the same species can present very different results. Hence, it is important to determine the energy partitioning for a particular organism under specific conditions, and to get a measure of a specific parameter it is necessary that organisms of the same sex, age and body size be compared under the same experimental conditions.

Abalone reared at 18°C and fed the formulated diets used 94% of the total energy consumed, with most of this energy channeled into somatic growth and respiration (Fig. 1). Conversely, individu-

als cultured at 22°C invested less energy in growth and almost 2.5 times more energy in reproduction than those cultured at 18°C. In other words, organisms cultured at 18°C expended more energy on somatic growth and less on reproduction than those reared at 22°C. Peck et al. (1987) obtained a similar energetic partitioning for abalone cultured at 15°C and fed fresh seaweed, reporting values of 83% absorption, 15.5% egestion and excretion, 34% growth and 20% respiration, though mucus production was 3-fold higher.

Depending on species, 50-g (dry weight) abalone have been reported to spend 88% (*H. tuberculata*), 74.5% (*H. midae*) and 104% (*H. kamtschatkana*) of the total energy consumed (Peck et al. 1987, Barkai & Griffiths 1988, Donovan & Carefoot 1998). However, abalone in this study cultured under the same conditions (15°C and fed fresh seaweed) but with a mean dry body weight of only 0.22 g, used ~60% of the energy assimilated. These differences are probably a result of an underestimation of the different variables of the energy budget assessed for abalone in this study. The importance of environmental effects on metabolism and physiology has been demonstrated in aquaculture management

(Brett & Groves 1979). Temperature has been considered one of the most important environmental factors controlling food utilization at all levels and all stages of growth in aquatic poikilothermic animals (Lovell 1989). The data obtained in this study clearly show that temperature and energetically-rich diets have a significant influence on somatic growth and reproductive investment. This information should be of use to aquaculturists and nutritionists in developing a formulated diet and determining the optimal culture conditions for *H. tuberculata*, and it contributes to the scientific knowledge of the associated physiological responses at different culture temperatures.

ACKNOWLEDGMENTS

THE HYPOBRANCHIAL GLAND FROM THE PURPLE SNAIL *PLICOPURPURA PANSA* (GOULD, 1853) (PROSOBRANCHIA: MURICIDAE)

LUDWIG C. A. NAEDEL* AND CARLOS AUGUSTO AGUILAR-CRUZ

Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional (CICIMAR/IPN) Apdo. Postal 592 LA PAZ, B.C.S. 23000 Mexico

ABSTRACT Results are presented on the histology of the hypobranchial gland of the marine muricid *Plicopurpura pansa* (Gould 1853). The general structure and secretory features were investigated using light microscopy and histochemical methods for the determination of tryptophan/indol. The hypobranchial gland of *P. pansa* is an antero-posteriorly elongated organ located on the internal surface area of the mantle, that folds on its posterior side near the rectum, right of the ctenidia and anterior to the kidney. In dead animals it is easily distinguishable by the purple color that develops after removing the shell. Parallel to the hypobranchial gland, in the same position, can be found a black-pigmented structure, presumably the anal gland. The secretory epithelium, which forms the hypobranchial gland consists of at least six different and very long (156.7 μ m) cell types. It was impossible to distinguish clearly the different histological regions of the hypobranchial gland, because the different cell types were uniformly distributed throughout the gland, with the exception of the rectal area. The number of acidophilic granular cells differed markedly between animals, probably because of different levels of secretion. In the mantle cavity was always found a large quantity of mucus and only occasionally acidophilic granulated secretory products. Only the two cell types with acidophilic granules in the hypobranchial gland showed histochemically strong positive reactions for tryptophan, indicating in these cells high concentrations of the precursors for "Tyrian Purple."

KEY WORDS: hypobranchial gland, purple snail, *Plicopurpura pansa*, Muricidae

INTRODUCTION

Most marine snails in the families Muricidae and Thaididae, which make up the genera *Murex*, *Thais* and *Plicopurpura*, produce in the hypobranchial gland (mucus gland) a viscous liquid secretion containing, besides mucus and biologically active compounds, minute amounts of chromogens. These develop enzymatically in light and oxygen into a purple pigment known as "Tyrian Purple," Royal Purple" or "Shellfish Purple." Fretter and Graham (1994) considered the main function of the hypobranchial gland to be a secretor of mucus for trapping and cementing particulate matter sucked into the mantle cavity with the respiratory water current prior to its expulsion.

The carnivorous, gonochoristic, marine, muricid purple snail *Plicopurpura pansa* (Gould, 1853) inhabits intertidal rocky shores exposed to high impact waves of the open sea. The range of *P. pansa* extends from the northwest coast of Mexico (Baja California Sur) (Clench 1947, Keen 1971) to northern Peru (Peña 1970, Paredes et al. 1999). The snail is not too small (shell length averages 30 mm but can be as large as 90 mm), and at low tides it is relatively easily gathered. An exceptional property of *P. pansa*, in comparison with that of other muricids, is that it ejects its dye-producing liquid in such large quantity, that there is no need to kill the animal to obtain the "Tyrian Purple." Furthermore, the hypobranchial gland is so active that the snails can be "milked" periodically without harming the animals (Rios-Jara et al. 1994, Naegel 2005). For these reasons it is not unexpected that *P. pansa* is exploited for "Tyrian Purple" production, probably since pre-Colombian times. In recent years however, with increasing public awareness of natural colors, the commercial exploitation of *P. pansa* for dyeing kimono with "Tyrian Purple" had reached in Mexico such levels as to threaten the survival of the species. In 1988 *P. pansa* had to be declared by the Mexican government a species under special protection (Anonymous, 1988; 1994). De-

spite these exceptional properties of *P. pansa*, first as a source for "Tyrian Purple" and secondly about the state of the endangered snail populations, little is known about the principal life-history features, and many basic biological questions remain. Until now studies are lacking on the histology of the hypobranchial gland of *P. pansa*. The objectives of this study are to gain a better understanding of the biological function of this gland (1) by examining the general morphological features of the *P. pansa* hypobranchial gland using compound light microscopy; (2) determining by histochemical means the inner-cellular sites of tryptophan and (3) comparing the results with previously published reports about the histology of the hypobranchial gland from other Muricidae and Thaididae.

MATERIALS AND METHODS

More than 100 specimens of an unexploited population of *P. pansa* were collected in 2001 from intertidal rocks on days during extreme low-water spring tides at Playa Cerrito on the Pacific coast (23°19'54"N and 110°10'38"W), about 80 km south-west of La Paz. The average size of the males was 25.87 mm (range 14.86–43.5 mm), of the females 30.14 mm (range 13–73.9 mm).

Injecting a 10% neutral, buffered, formalin solution into the snails preserved the tissue of the animals. About 24 h later in the laboratory eight animals were selected and removed from the shell, subsequently dehydrated in an alcohol series, cleared with butylated hydroxyanisole, and embedded in paraffin. Longitudinal and transversal sections (5 μ m) were prepared of the hypobranchial gland, and according to the methodology by Humason (1979), stained with Ferric Hematoxylin-Eosin or Mallory Trichrome stain. To prove the presence of tryptophan, as the origin of the precursors for "Tyrian Purple" (Verhecken 1989), the histochemical method for the demonstration of tryptophan (Davenport 1960) was applied.

RESULTS

The hypobranchial gland of *P. pansa* is an antero-posteriorly elongated organ located at the internal surface area of the mantle,

*Corresponding author. E-mail: lnaegel@ipn.mx

that folds on its posterior side near the rectum, right of the ctenidia and anterior to the kidney (Fig. 1). On dead animals it is easily distinguishable by the purple color that develops after the removal of the shell. Parallel to the hypobranchial gland in the same position can be found a black pigmented structure, presumably the anal gland.

The secretory epithelium, which forms the hypobranchial gland consists of at least six different and very long (156.7 μm) nonciliated cell types: (a) eosinophilic cells with an irregular cytoplasmic texture, (b) very abundant goblet mucus cells, (c) cells with strong acidophilic granules, (d) cells with light acidophilic granules, (e) a few cells at the rectal area with very fine basophilic granules and (f) empty cells.

Figure 2 shows a section of the hypobranchial gland: the basal membrane with the longitudinal muscle cells, eosinophilic and goblet mucus cells and cells with acidophilic granules. At the right side of the photograph is shown the mantle cavity with secreted mucus and acidophilic granules. At the left side is shown the external cubical epithelium, which is in contact with the shell.

It was impossible to distinguish clearly the different histological regions of the hypobranchial gland because the different cell types were uniformly distributed in the gland. The exception was the rectal area—the only region where a cell type was found with very fine basophilic granules and where the number of mucus cells and cells with acidophilic granules was reduced. Along the glandular epithelium in the basal tissue were found a few blood vessels and a thin layer of longitudinal smooth muscle fibers.

The number of acidophilic granular cells in the hypobranchial gland differed markedly between different individuals, probably, because of the different stages of secretion. In the mantle cavity there was always a large quantity of mucus (Fig. 3), and only occasionally acidophilic granular secretory products.

Adjacent to the secretory epithelium of the hypobranchial gland is located an acinous glandular-like structure, which could be the rectal or anal gland. The acini are composed of small (10 μm) nonciliated cubical cells with a large quantity of fine and dark staining basophilic granules. No products of secretion were observed in the lumen of the acini, nor in the duct, which connects to the mantle cavity, the rectum, or the exterior of the snail (Fig. 4).

Only the two cell types with acidophilic granules in the hypo-

branchial gland showed a histochemically strong positive reaction for tryptophan, indicating that in these cells there are high concentrations of the precursors or chromogens for "Tyrian Purple."

DISCUSSION

In the Old World the production and use of "Tyrian purple" was forgotten with the fall of Byzantium (Constantinople) in 1453 A:D. Therefore, it was a big surprise to the scientific community when more than 200 y later, in 1685, William Cole was informed that at the coast of Ireland "Tyrian Purple" from marine snails was still used to mark fine linen (Cole, 1685). After many trials with different snail species at Minehead in England he found the means to obtain the precursors of "Tyrian Purple" from the muricid *Nucella lapillus*, and the procedure for dyeing materials with them to obtain the final pigment. He made the important observation, first,

that as soon as the colorless fluid is exposed to air and light it becomes immediately yellow and greenish. Soon afterwards it turns into deep emerald green, blue, deep blue, and finally reaches the purple color; and, second, that for this stepwise chemical process light and air are needed. However, 30 y before the discovery by W. Cole about the use of "Tyrian Purple" in Ireland, the English priest Thomas Gage (1655) reported from the New World, Nicoya (Costa Rica), about the commercial exploitation of the secretions of the hypobranchial gland of *P. pansa* to dye garments for rich Spaniards.

Lacaze-Duthiers (1859) showed that the precursors for the pigments are not formed in the kidney or in a vein, as thought during his time, but in a band-like glandular epithelium located at the superior part of the internal mantle cavity. However, because of missing acini and excretory ducts he considered the glandular epithelium not to be a gland. His histological studies of the hypobranchial epithelium of muricids and thaidids raised the interest of many scientists to describe in more detail the histology of the hypobranchial gland.

Letellier (1890) observed in the hypobranchial epithelium of *Purpura lapillus* that the purple producing cells in the middle part of the purple band are much larger, than the neighboring cells. During the same year Bernard (1890) found well-developed innervations in the base of the hypobranchial epithelium of *P. lapillus*, and described that the activity of neuro-epithelial cells has an impact on the production of mucus.

Ersparmer (1946) showed by histochemical methods that in muricids the purple precursors and the enzyme "purpurasi" are localized in the median zone of the hypobranchial body and are kept separate, so that no reaction occurs. Hunt (1973) grouped the many different secretory cell types into two main categories: (a) acid mucin cells and (b) goblet cells. He did not include the purple producing cells. Additionally, as Bernard (1890), he found nerve cells on the base of the gland. Astonishingly, these nerve cells are not in contact with the secretory or purple producing but with ciliated cells (Hunt 1973).

Bolognani-Fantin and Ottaviani (1981) in a histochemical study observed in the hypobranchial gland of *M. brandaris* different cell types: (a) granulated cells with large, and fine granules, (b) with a homogenous cytoplasm, (c) ciliated cells having no impact

on the secretion and (d) empty cells. The different granulated cells, which are only found in the middle area, could reflect different stages of purple production. In another histochemical study of the hypobranchial gland of the marine muricid *Morula granulata* Srilakshmi (1991) described a similar basic arrangement of cells, like described before by Bolognani-Fantin and Ottaviani (1981) and noted the presence of neuro-sensory cells, which form the hypobranchial nerve. Roller et al. (1995) studying by means of light and electron microscopy the hypobranchial gland of the estuarine snail *Stramonita* (= *Thais*) *haemastoma canaliculata* defined three anatomically and histologically different areas with eight distinct cell types, which are randomly distributed in the gland. Among these only one is ciliated, a cell type with acidophilic granules. Others are secretory cells that release large amounts of mucus into the mantle cavity.

We observed the same basic types of cells and the great similarity between the previously described hypobranchial glands of different muricids and thaidids. According to Bolognani-Fantin and Ottaviani (1981) the great number of different cells with different functions is a characteristic of the hypobranchial gland of "Tyrian Purple" producing species. Bolognani-Fantin and Ottaviani (1981) mentioned that the hypobranchial gland of a freshwater (*Viviparus viviparus*) and of a terrestrial (*Pomatias elegans*) snail species show a much simpler glandular structure. Bolognani-Fantin and Ottaviani (1981) observed additionally that the cells with fine acidophilic granules react positively to phenolic and indolic substances, which are considered as "Tyrian Purple" precursors. This was confirmed by Srilakshmi (1991) who found strong reactions for tryptophan and tyrosine in the hypobranchial gland. Bolognani-Fantin and Ottaviani (1981) and our results show that only the cells with acidophilic granules react positively to tryptophan. Therefore the acidophilic granulated cells found by Roller et al. (1995) in the hypobranchial gland of the muricid *S. haemastoma canaliculata* could be the purple producing cells.

Lacaze-Duthiers (1859) observed that when the animal contracts vigorously the cells massively open by mechanical or osmotic pressure dispersing their contents into the mantle cavity. Because of the minimal quantity of muscle fibers around the hypobranchial gland of all the earlier mentioned muricids, the likelihood of muscular stimuli is uncertain. Release of the secretion also could be stimulated by neurosecretory activities, because of the presence of neurosensory cells that form the hypobranchial nerve (Srilakshmi 1991). However, there is no evidence of a connection between the nerve and the secretory cells.

Bolognani-Fantin and Ottaviani (1981) mentioned the presence of picrophilic granules on both lateral sites of the hypobranchial gland that reacted with indole, but they could not relate them to the production of mucus or purple. Both authors also mentioned that in the hypobranchial gland of *Murex brandaris* no structural or chemical differences could be observed during the different seasons of the year.

The large number of different cell types and many possible chemical activities in the hypobranchial gland are an indication that the gland has multiple biological functions. These are yet to be discovered.

ACKNOWLEDGMENTS

The authors acknowledge thankfully the support for this study from CONACYT (Project 31566-N) and from CGPI, COFAA and EDI (Instituto Politécnico Nacional, México). A part of this study

formed the basis for C.A. Aguilar-Cruz of his Licenciatura in Marine Biology. We are thankful for all the comments, critics, and

CAN THE COLLECTION OF “TYRIAN PURPLE” FROM *PLICOPURPURA PANSA* (GOULD, 1853) (PROSOBRANCHIA, MURICIDAE) BE BLAMED FOR ITS DECLINING POPULATION?

LUDWIG C. A. NAEDEL* AND JORGE A. LOPEZ-ROCHA

Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional (CICIMAR-IPN) Apdo. Postal 592 LA PAZ, B.C.S. 23000, Mexico

ABSTRACT Marked, sized and sex determined purple snails *Plicopurpura pansa*, (Gould, 1853) were distributed randomly among other snails in crevices of an intertidal rocky island splashed during high tides by high impact waves. After 89 days 18%, after 117 days 12%, after 145 days 8% and after 183 days only 3% of the marked snails could be recovered. There was no statistically significant difference between size and sex and the recovery rate. In the laboratory we determined the time needed for reattachment to the surface under different situations. Snails placed with the aperture down on a wet surface or in water reattached themselves after about 20 min, snails placed in water on their backs; in about 40 min, and snails left on a wet surface on their backs after 2 hours. After 4 hours only 50% of the snails placed on their backs in a wet surface were found to be reattached. Great differences were noticed in the period needed for reattachment among individual snails. The time needed for the snails to overcome the stress of being detached from the surface and to reattach themselves again can be blamed for the loss of animals during the increasing incoming tides combined with the high impact wave actions. The prohibition of “milking” *P. pansa* to obtain “Tyrian Purple” and to collect the snails as a bait for fishery or as a special food for foreigners should be enforced and should be extended to the removal the snails from the crevices of intertidal rocks.

KEY WORDS: purple snail, *Plicopurpura pansa*, muricidae

INTRODUCTION

In antiquity, the “Tyrian purple” from the Mediterranean muricids, *Murex trunculus*, *M. brandaris* and *Purpura haemastoma* was used extensively to dye materials for the nobility. Because of the enormous number of snails to be killed for the extraction of a minute amount of the chromogens produced by the hypobranchial gland, the scarcity of the snails, and the technical difficulties to obtain the final dye explains why “Tyrian Purple” was at that time a most expensive luxury article. A remarkable exception amongst the muricids is *Plicopurpura pansa* (Gould, 1853) from the Pacific coast of Central America and Mexico, because this mollusc ejects its dye-producing liquid in such a quantity that there is no need to kill the animal to obtain the purple. Furthermore, the dye-producing hypobranchial gland is so active that the snails can be “milked” periodically without harming them (Rios-Jara et al. 1994, Naegel 2005). It is possible that “Tyrian Purple” from *P. pansa* was used on the Pacific coast of Central America and Mexico before Columbus, however our current knowledge about this is very limited. During the Spanish rule, the peninsula of Nicoya in Costa Rica was center for the production of “hilo morado,” which played an important commercial role for the church to charge for their services in “hilo morado,” and for the “gold-hungry” Spanish magistrates to obtain an income from exports to Central and South America. The high demand for “hilo morado” resulted in a decreased population of *P. pansa*, even leading in 1760 to an uprising of the indigenous people in Nicoya against the Spanish administration (Fernández-Guardia 1938, Jinesta 1940). From written reports it is seen that at the end of the 19th century indigenous people from Mexico (Martens, v. 1874) and Nicaragua (Schunck 1880) dyed textiles with “Tyrian Purple” obtained from *P. pansa*. Von Martens mentioned that the high value of purple dyed skirts is explained by the high number of snails needed, which are not numerous at Tehuantepec (Oaxaca) (Martens, v. 1898). In 1909, the ethnologist Zelia Nuttall visited Tehuantepec, and she also reported that the population of the purple snails seemed to be

over-exploited and became scarce, in spite of the careful treatment of the snails during the “ink” collection (Nuttall 1909). In recent years, with the increasing interest in natural colors, the commercial exploitation of the purple snail for dyeing kimonos with natural “Tyrian purple” had reached in Mexico, in the States of Oaxaca, Nayarit, Guerrero and Michoacan, such levels as to threaten the survival of the species (Castillo-Rodríguez & Amezcua-Linares 1992, Acevedo-García 1995). In 1988 *P. pansa* had to be declared a species under special protection by the Mexican government (Anonymous 1988, Anonymous 1994).

Like following a golden thread in the history of the exploitation of *P. pansa* for the production of “Tyrian Purple” it can be observed that it resulted in a decrease of the snail population, in spite of careful treatment of the snails during the “ink” collection and replacement afterwards on the rocks where they have been previously removed. Naegel (2005) has shown that removing the snails from the surface, and Rios-Jara et al. (1994) and Naegel (2005) have demonstrated that periodically collecting the secretion of the hypobranchial gland does not harm the animals. What are the reasons for the declining snail population after “milking”? In a previous study Ramírez-Rodríguez and Naegel (2003) suggested that the snails are just washed away by high impact waves from the rocks after “milking” before being able to attach themselves. In this study this suggestion will be followed up under natural conditions with marked and recaptured snails of different sizes and sexes. Snails reared in the laboratory were used for the determination of the time needed to reattach themselves to the surface after being removed. The results will serve as a prerequisite for the planning, site selection and management of the potential exploitation of *P. pansa* for its “Tyrian purple.”

MATERIALS AND METHODS

In the laboratory at CICIMAR (La Paz, Baja California Sur, Mexico) from 431 *P. pansa* snails the size and sex were determined and afterwards they were tagged with colored and numbered marks as used in bee-keeping. On November 11, 2005 the snails (266 males with an average total shell length of 27.9 mm; range 17.5–44.4 mm and 165 females with an average total shell

	N	SD	n	SD
17.5–26.4	90	1.78	40	1.99
26.5–35.4	165	2.46	88	2.32
35.5–47.4	11	2.77	37	2.61
Total	266	4.04	165	5.54

SD = Standard deviation

length of 30.36 mm; range 18.2–47.4) (Table 1) were transferred to Playa Cerritos (23°19'49"N, 110°10'45"W) (Fig. 1) about 120 km southwest of La Paz, Baja California Sur, Mexico and placed randomly amongst other *P. pansa* snails in crevices on an intertidal rocky island. At low tide the basalt rock covers an area of about 800 m², from which, even at low tides, are accessible only about 400 m² because of the high impact waves striking the rock. The island has several elevated points, the highest with 3.04 m above the mean tide water level, with many crevices located opposite the impact of the waves. We determined in a rough estimate that only about 1/8th of the total rock area is suited as a habitat for *P. pansa*.

The island was revisited during extreme low tides after 89, 117, 145 and 183 days, the marked animals recaptured, and afterwards placed carefully amongst other snails in crevices. The number and size of the recaptured marked snails was examined to determine possible effects of size and sex on the rate of recovery, and χ^2 test

applied to determine significant differences. A level of significance of $P < 0.05$ was applied.

In the laboratory we determined the time needed for snails of different sizes ($n = 382$, average size: 32.2 mm, size range: 19–46.1 mm, $SD \pm 4$ mm) and sex (males: $n = 96$, average size: 32.2 mm, size range: 24.3–44 mm, $SD \pm 3.8$ mm; females: $n = 96$, average size 33.5 mm, size range: 23.1–46.1 mm, $SD \pm 4.6$ mm) to reattach. For each position of the snails we repeated the experiments four times. We used a transparent plastic tray with a 5-cm wall height to observe the attachment of the foot of the snails to the surface. In the experiments with snails lying on their backs on the wet surface and after 4 hours remaining unattached to the surface we had to sprinkle a few drops of seawater on the operculum to prevent dehydration of the animals. To determine whether possible differences exist between laboratory and field snails in the time for reattachment required, we performed two additional experiments at Playa Cerritos with snails ($n = 48$; average size: 28.7 mm; size range: 22–36.9 mm; $SD \pm 3.8$ mm).

The differences in the time needed for reattachment to the surface in the field and in the laboratory among the different size classes and sex were determined by 1-way ANOVA. The Tukey test was further used to determine significant differences and $P < 0.05$ was used as the significance level.

RESULTS

On November 11, 2004, during an extreme low tide (tidal difference between low and high tide: 1.89 m), 431 marked snails were placed randomly amongst other *P. pansa* snails in crevices of the intertidal rocky island.

After 89 days (difference between low and high tide of more than 2 m) 77 marked snails were recovered (57 males and 20 females), after 117 days 52 animals (19 females, 33 males), after 145 days 36 snails (12 females and 24 males) and after 183 days (difference between low and high tide: 1.30 m) 13 animals (no females and 13 males). To determine if the size of the animals had an impact on the likelihood of recovery, the recovered snails were divided into three size classes. Table 2 shows in three size classes the number of recovered females and males during the experimental period. After 89 days from the size class 17.5–26.4 mm 27% of the animals were recovered. From the size class 26.5–35.4 mm 14% of the snails were recovered. From the larger size class (35.5–47.4 mm), after 117 days, not one male and after 145 days only one female was recovered. After 183 days of the experiment not one female was recovered from all three size classes, and from the male snails 7% from the smallest and only 3% from the medium size group. No statistical differences were found among the three size classes.

In the laboratory we determined the time needed for reattachment of the snails to the surface. Great differences were observed between individual snails and the time needed for their reattachment. These individual differences could not be statistically related to the size or sex of the animals ($P > 0.05$). For animals placed on their backs on a wet surface, it took an average of more than 2 hours for reattachment (Fig. 2). Seventy percent of the snails placed with the aperture down on the wet surface, or in water, reattached themselves on the surface only after 20 min. and 90% of the snails were reattached after 1 h (Fig. 3). There was no statistic difference ($P > 0.05$) in the time needed for reattachment between snails placed on the aperture in water and on a wet surface. Animals placed on their backs on the wet surface and in water behaved differently. A statistical difference ($P < 0.05$) was found

Figure 1. Location of Playa Cerritos and of La Paz, Baja California Sur, Mexico.

TABLE 2.

Size classes of *P. pansa* snails recaptured at Playa Cerritos, Baja California Sur, Mexico, after 89, 117, 145 and 183 days.

Size (mm)	89 Days		117 Days		145 Days		183 Days	
	Number	%	Number	%	Number	%	Number	%
17.5–26.4	35	27%	15	12%	10	8%	7	5%
26.5–35.4	36	14%	34	13%	25	10%	6	2%
35.5–44.4	6	13%	3	6%	1	2%	0	0%
Total	77	18%	52	12%	36	8%	13	3%

among animals placed their backs on the wet surface and the other three groups. After 2 hours, 80% of the snails on their backs in water turned over on their aperture and attached themselves to the surface, and after 6 hours 86% were attaching. From the 96 snails placed on their backs on the wet surface, only 50% were attached after 4 hours. After 4 hours the remaining 48 snails received a few drops of seawater on the operculum and the animals revived, and after 6 hours 86% of the snails were found attached to the surface (Fig. 3). This result shows the danger, for snails lying for longer periods in the dry on their backs, of being desiccated (Fig. 3).

We determined at Playa Cerritos the time needed for reattachment of snails placed with the aperture down and in water. The average time for reattachment took 11.7 min (SD \pm 13.5 min). A result, which is statistically not different ($P < 0.05$) to the findings from the laboratory tests described before.

DISCUSSION

The recapture rate of snails placed carefully into crevices was astonishingly low. After 89 days of the 431 snails only 18% were recovered, mainly (27%) from the smallest size class. It is more likely for large and not yet attached animals to be swept away by strong waves. After 183 days of the experiment only 3% of the animals (13) were recovered. Wave-swept shores, like the intertidal rocks at Playa Cerritos, are physically harsh environments, and only crevices give the snails protection from not being washed away by high impact waves during high tides. *P. pansa* is a most spatially restricted species and over 75% is found primarily in crevices (Garrity, 1984). This microhabitat is important in reducing temperature and water loss. *P. pansa* is extremely sensitive to

heat and desiccation on open surfaces. Animals removed from the crevices during daytime low tides reach higher tissue temperatures, lose more mass and suffer higher mortalities than control animals (Garrity 1984). Removing the snails carefully from the surface and replacing them afterwards in water does not cause mortalities (Naegel 2005). This finding is in contrast to the report by Castillo-Rodríguez and Amezcua-Linares (1992) who blamed the mortalities on the brusque removal of snails from the crevices, and the bending of the operculum and the muscular foot for the extraction of the dye precursors. Acevedo-García (1995) mentioned differences in the way commercial "ink-collectors" and traditional indigenous people remove the snails from the crevices in the rocks: not to harm the animals the indigenous people use a wooden stick in the form of a spatula, the "ink-collectors," however, use a hook made out of wire, which sometimes breaks the shell. Acevedo-García (1995) also mentioned the different methods used by indigenous people and commercial "ink-collectors" to obtain the dye secretion. To stimulate the expulsion of the "ink" the indigenous people spit and/or blow on the operculum, in contrast to the commercial "ink-collectors" who press the operculum with the thumb, which causes a weakening of the fixation of the animals to the rocks, from where they can easily be washed away by the strong waves. Some "ink collectors" place the snails after "milking" together with their "milk" in a small pot. The narcotizing compounds in the "milk" reduce the capability of the snails, after their release, to attach themselves fast enough, and consequently are in danger of being washed away.

During our field experiments we didn't use a spatula or a hook to remove the snails from the crevices so as not to hurt them. We replaced carefully the snails again in crevices. Despite all this care the recovery rate was very low.

The removal and the "milking" of the purple snails cannot

Figure 2. Average time needed by *P. pansa* snails to reattach themselves after removal to the surface. A = Aperture down on a wet surface ($n = 94$), B = Aperture down in water ($n = 96$), C = Snails on the back of the shell on a wet surface ($n = 96$), D = Snails on the back of the shell in water ($n = 96$). Columns with different superscripts are statistically significantly different ($P < 0.05$). Bars represent standard error.

Figure 3. Time needed by *P. pansa* snails for the reattachment to the surface after removal. A = Aperture down on a wet surface, B = Aperture down in water, C = Snails on the back of the shell on a wet surface, D = Snails on the back of the shell in water.

alone be blamed for its declining population. The main reason is the time needed for reattachment to the surface, especially when the snails are placed on their backs and in dry locations. The attachment of the snails after replacing them on the surface takes too long and does not prevent them being washed away by the incoming tides. The period from "milking" until the attachment is a very critical phase for these animals. In the laboratory tests it took 2 hours for reattachment for 50%, and six for 80% of the animals placed on the back and on a wet surface. As soon as the animals are attached by their large foot muscle to the surface they are relatively safe from being displaced. Additionally the strong shell gives *P. pansa* protection against destruction by the waves. The removal of the purple snail from rocks causes a never-before-experienced situation and stress to the snails. Individuals respond in different ways by needing different periods for reattachment to the surface. The careful replacement of the snails after their removal from the rocks with the aperture down, on a moist surface or even in water, helps them to recover from the stress, and to reattach themselves. However, even under the most careful conditions of replacement some snails need long periods before reattachment and are in danger of being washed away during the approaching high tides with their high impact waves.

Today's commercial "ink-collectors" work under piecework conditions: the larger number of skeins dyed with the secretion of the snails in less time results in higher profits, but also inevitably in a larger number of snails "milked" and less care for their reattachment and conservation (Acevedo-García 1995). In the past a similar situation existed in Costa Rica where the indigenous people had to fulfill the demands for "hilo morado" by the Spanish ad-

ministrators and priests. This rush of work often results in the snails not being removed carefully from the rocks, not "milked" with care and at the end are left exposed to the strong wave actions of the sea or to the sun thus causing the death of the animals. Additionally, because female snails reach larger sizes than males and because of their larger size expel more secretion, they are preferred by "ink" collectors. Furthermore, the collection, especially of larger-sized purple snails as a special food for foreigners, is a recent development, which causes a reduction in recruitment and a decrease in the snail's population. However, not only the activities of collectors of the purple snail but also the increased effects in recent years of water contamination can be blamed for the decrease in snail populations (Castillo-Rodríguez & Amescua-Linares 1992).

A strict enforcement of the prohibition of collecting *P. pansa* is needed for the conservation of the purple snail, yes, even the prohibition to remove snails from the crevices of wave swept rocks. Additionally intensive research is required for the controlled reproduction to restock over-exploited areas.

ACKNOWLEDGMENTS

The authors thank Irma Castañon-Estrada and Anabel Rosales-Maldonado (U.A. Nayarit) for their help in determining the sex of the snails. Special thanks to Chris Cooksey for making suggestions to improve earlier versions of the manuscript and to the anonymous reviewers for their comments and corrections. This work was supported by grants from CGPI, COFAA and EDI (Instituto Politécnico Nacional, Mexico).

ABSTRACT Although studies of this species have focused on its reproductive cycle, there is no literature available on the ultrastructure of its germ cells. This study consequently aims to describe the latter cells as well as the shape of the acrosome, a character that may be of help in the taxonomic allocation of species of this family or other bivalve families. Results indicate spermatogonia have a central, spherical nucleus as well as scattered heterochromatin granules throughout the nucleoplasm. Rough endoplasmic reticulum is scarce, but the cytoplasm is rich in mitochondria and disperse glycogen granules. In primary spermatocytes, heterochromatin is more highly condensed and there is a reduction in the amount of cytoplasm and number of mitochondria as compared with spermatogonia. In secondary spermatocytes, heterochromatin is present in peripheral areas of the nucleus, forming occasional projections towards its center. In spermatids chromatin is fully condensed, taking up the entire nucleus. Mitochondria increase in size and migrate to the basal pole, giving rise, along with the centriole, to the spermatozoon neck. In spermatozoa, the nucleus is ovoid, the acrosome is round and the centriole is surrounded by four mitochondria, unlike other bivalves, like *Anadara tuberculosa*, in which the nucleus is reported to be round, the acrosome is pyramidal and there are five mitochondria.

KEY WORDS: white clam, *Chione*, spermatogenesis, ultrastructure

INTRODUCTION

The white clam, *Chione californiensis* (Broderip, 1835) is a bivalve mollusc of the family Veneridae, a group regarded as a potential fishery and aquaculture resource (Baqueiro 1987). One of several species exploited by the traditional fishing industry along the coasts of the Sea of Cortéz, it is for the most part a local food item (Baqueiro 1989). The reproductive cycle of several species of the genus *Chione* in Mexico has been described previously. García-Domínguez et al. (1993), in particular, have described the gonadal cycle of *Ch. californiensis*.

The ultrastructure of the spermatozoa has been described in many bivalve genera, such as *Bamia candida* (Pasteels & Harven 1962), *Hyriopsis schlegelii* (Higashi 1964), *Turtonia minuta* (Ockelmann 1964), *Mytilus edulis* and *M. perna* (Nijima & Dan 1965, Bourcart et al. 1965), *Spisula solidissima* (Longo & Anderson 1969), *Corbicula sandai* (Hachiri & Higashi 1970), *Crassostrea virginica* (Galtsoff & Philpott 1960, Daniels et al. 1973), *Bankia* spp. (Popham et al. 1974), *Lyrodus* spp. and *Teredo* spp. (Popham 1974), *Ligumia rostrata* (Trimble & Gaudin 1975), *Nucula hartvigiana* (Popham & Marshall 1977), *Anadara trapezia*, *Anomia descripta*, *Fulvia tenuicostata*, *Myodara brevis* and *Notocorbula vicaria* (Popham, 1979).

The ultrastructure of the different germ cells occurring during spermatogenesis and spermiogenesis was described in *Anadara granosa* by Suwanrajat and Parnrong (1999) and by Ortiz et al. (2003) in *A. tuberculosa*. Differences were found as to number of mitochondria and acrosome shape. Our study thus aims to describe the ultrastructure of these cells in *Ch. californiensis*, a factor that may help significantly to improve the taxonomic allocation of different bivalve species.

MATERIALS AND METHODS

Male specimens were collected in an intertidal coral reef located north of Ensenada de la Paz, a coastal lagoon lying southwest of Bahía de la Paz, B.C.S., Mexico, at 24°06' to 24°10'N and 110°19' to 110°25'W. Small samples of gonad tissue were removed and fixed in 2.5% glutaraldehyde in seawater with a pH of 8 for 48 h, then rinsed with 2.5% sodium bicarbonate and postfixed with osmium tetroxide for 1 h (Buckland et al. 1986). Dehydration was done in three 10-min shifts with different concentrations of ethanol, followed by two 20-min propylene oxide shifts. Samples were then permeated with 1:1 propylene oxide/epoxy and embedded in Epon 812. Very thin 70-nm sections were obtained and set in mesh copper grids. These were treated with uranyl acetate and lead citrate to enhance contrast and later examined under the transmission electron microscope (Jeol-100SX).

RESULTS

The first germ cells to mature during spermatogenesis are spermatogonia, which have a large central nucleus and, typically, heterochromatin granules of varied size scattered throughout the nucleoplasm. The cytoplasm is rich in mitochondria, whereas rough endoplasmic reticulum, found near the nucleus, is scarce (Fig. 1A).

Primary spermatocytes are formed by mitosis of the spermatogonia. The nucleus has a larger amount of condensed heterochromatin, but there is less cytoplasm and fewer mitochondria than in spermatogonia (Fig. 1B). Primary spermatocytes give rise by meiosis to secondary spermatocytes. Heterochromatin is characteristically more condensed in the latter, migrating to peripheral areas of the nucleus (Fig. 1C).

Spermatids arise from secondary spermatocytes, which have become significantly smaller. There is less cytoplasm and it forms a halo around the nucleus. Chromatin takes up all of the latter and it is fully condensed. During this stage, mitochondria increase in size and migrate to the basal pole of the nucleus (Fig. 1D).

Figure 1. (A) Spermatogonia. Randomly scattered heterochromatin (H). Abundant mitochondria (arrows) are shown. (B) Primary spermatocyte. Condensed heterochromatin (H) and scarce mitochondria (arrows) are observed. (C) Secondary spermatocyte. Heterochromatin is localized peripherally (H) and mitochondria (arrows) are shown. (D) Spermatid. Chromatin is completely condensed (H) and mitochondria are increased in size (arrows). Bar = 0.5 μ m.

Lastly, spermatids undergo a complex change during spermiogenesis giving rise to spermatozoa, which display three regions: head, middle piece and tail. The head is formed by an elongate nucleus and a round acrosoma (Fig. 2A). The neck or middle piece contains four mitochondria with well-developed cristae arrayed in a circle (Fig. 2B). Central to the four mitochondria lies the centriole, which gives rise to the flagellum. The latter exhibits the typical axoneme structure of nine paired peripheral microtubules and two central ones.

DISCUSSION

During the first two stages of spermatogenesis involving maturation of the spermatogonia, in the course of formation of the

primary spermatocytes, which undergo mitotic multiplication to give rise to secondary spermatocytes and during meiosis of the secondary spermatocytes in the course of which spermatids arise, germ cells contain a large central nucleus with heterochromatin granules of varied size and there are few organelles. In spermatids, chromatin is fully condensed and a reduced cytoplasm forms a halo about the nucleus, whereas mitochondria increase in size and migrate to the basal pole of the nucleus. These characters are similar to those reported by Suwanrajat and Parnrong (1999) in *Anadara granosa* and Ortiz et al. (2003) in *A. tuberculosa*.

During spermiogenesis the name given to the last stage of spermatogenesis spermatids are fully transformed to give rise to spermatozoa. Existing characters confirm the primitive nature of the latter, as in several other bivalves with external fertilization (Franzén 1955).

Figure 2. (A) Spermatozoid. Pyramidal acrosome (Ac), centromere (*), mitochondria (arrows) and flagellum (F) are shown. (B) Typical four mitochondria (arrows) and centromere (*). Bar = 0.5 μ m.

The acrosome of molluscs varies widely as to size, composition, morphology and position in spermatozoa. Arising usually in a vesicle derived from the Golgi body (Popham 1979), its function is to dissolve the various egg layers so that fusion of spermatozoon and ovum can occur (Colwin & Colwin 1967, Franklin 1970, Longo 1973). *Chione californiensis* has a round acrosome, unlike *A. tuberculosa* where the latter is pyramidal (Ortiz et al. 2003) and *A. granosa* in which it is triangular (Suwanrajat & Parnrong 1999).

The spermatozoon nucleus displays great morphological diversity in mollusc species. In spermatozoa of a primitive type the nucleus may be spherical, ovoid or conical (Popham 1979). Franzen (1955, 1970) mentions this structure is used as a systematic character.

Mitochondria are usually spherical in shape and their array as spherical masses on the proximal end of the spermatozoon head is also typical of species with external fertilization. Suwanrajat and Parnrong (1999) say the number of mitochondria may be species specific. Five mitochondria are present in *A. tuberculosa* (Ortiz et al. 2003) and four in *Ch. californiensis*, confirming the fact that this may be a species specific character.

Axoneme structure of the flagellum varies little in bivalve molluscs. It is comprised of a central pair of microtubules, which is surrounded by nine peripheral pairs (Ortiz et al. 2003). This concurs with our observations in *Ch. californiensis*.

We may conclude from this that the spermatozoa of *Chione californiensis* exhibit as species specific characters an ovoid nucleus, a round acrosome and a centriole surrounded by four mitochondria.

OUT-CROSSING AMONG COMMERCIAL STRAINS OF THE NORTHERN QUAHOG, *MERCENARIA MERCENARIA*: SURVIVAL, GROWTH AND IMPLICATIONS FOR SELECTIVE BREEDING

MARK D. CAMARA,^{1,2*} STANDISH K. ALLEN, JR.,¹ RYAN B. CARNEGIE¹ AND KIMBERLY S. REECE¹

ABSTRACT Because the accumulation of inbreeding within hatchery-propagated stocks of the hard clam, *Mercenaria mercenaria* (Linnaeus, 1758), could result in reduced growth and survival, we studied the potential for improving performance through out-crossing among existing hatchery strains. We produced all 10 possible out-crossed combinations among 5 strains of clams as well as all 5 pure parental strains simultaneously in the hatchery and measured their size at the time of metamorphosis (the spat stage) and at the end of a nursery period in mesh bags at a single field site (the seed stage). We then planted replicate plots of all fifteen strains at five field sites in Virginia, USA encompassing the range of salinity conditions used by commercial growers, and monitored growth and survival for two growing seasons. We found significant phenotypic differences among strains at the spat and seed stage, but different strains performed best at each stage. In the field we found significant site effects, strain effects and strain-by-site interactions, but there was no evidence of negative correlations in performance among sites indicating strong trade-offs that would be problematic for selective breeding. Three different linear contrasts designed to compare out-crossed and pure strains for each parental stock, test for nonadditive genetic effects within each pairing of different parental strains, and estimate the general combining ability of parental strains reveal a complex pattern. We found both inbreeding and out-breeding depression depending on the developmental stage of the clams and the parental strain examined. Within strain crosses generally produced larger spat but smaller seed. Out-crossed progeny were generally smaller at the spat stage than the average of their parental lines but larger at the seed stage. The two best performing parental strains had significant, positive, general combining abilities, whereas this measure was negative for the two worst parental strains. In the field, inbreeding depression was restricted to lines that showed poor pure strain performance, and these strains also showed poor general combining ability, whereas strains with good pure line performance showed out-breeding depression and good general combining ability. Only the poorest performing pure parental lines showed non-additive effects when we compared each out-crossed strain to the mean of its parental strains, suggesting that heterotic effects are unlikely to be useful for selective breeding. Finally, there were significant correlations between seed measurements and field performance indicating that it may be possible, in the context of selective breeding programs, to weed out inferior strains or families early in the life cycle.

KEY WORDS: *Mercenaria mercenaria*, hard clam, northern quahog, breeding, genetics, heterosis, inbreeding

INTRODUCTION

On the eastern coast of the United States, the hard shell clam or Northern quahog, *Mercenaria mercenaria* (L.), is the most valuable aquaculture product produced. Wild populations historically supported a large subsistence, commercial and recreational fishery, but harvests have recently declined in many areas—probably caused by problems with water quality and overharvesting. On the other hand, the aquaculture sector of the hard clam market has been growing rapidly for the last 10–15 y and clams are now cultured from Massachusetts to Florida. USDA figures indicate that the economic value of the clam aquaculture market grew from approximately \$5 million in 1995 to approximately \$38 million in food products and \$1.2 million in seed clams in 1998 (Anonymous, 2000).

Despite the coast-wide economic importance of this species and the clam farming industry, there have been relatively few genetic studies of *M. mercenaria*, and selective breeding and domestication efforts have been largely limited to informal programs of mass selection conducted by commercial seed producers without rigorous genetic analysis (Gallivan & Allen 2000). The few genetic data available, along with anecdotal information from growers and hatchery operators, indicate that traits of economic interest such as growth and survival are heritable in hard clams

(recently reviewed by Hilbish 2001). Chanley (1960) reported that selection was able to improve growth in a population started from just three crosses. Hadley et al. (1991) reported a wide range of heritability estimates for growth (0–0.43), and Rawson and Hilbish (1990) reported a heritability of 0.37 for growth during the first 6 mo postspawning. Commonly cultured strains differ markedly in susceptibility to QPX disease, indicating a high degree of genetic control over this trait as well (Ford et al. 2002, Ragone Calvo & Bureson 2002, Ragone Calvo et al. 2003). In addition, some aspects of shell coloration appear to have a relatively simple genetic basis (Chanley 1960). All indications, therefore, are that domestication and selective breeding of hard clams could result in marked improvement of economically important characters.

Complicating matters for would-be shellfish breeders and commercial growers alike, however, is the finding that genotype by environment interactions for growth and survival are common in bivalves, including *M. mercenaria* (Hilbish et al. 1993, Newkirk 1978b, Rawson & Hilbish 1990, Rawson & Hilbish 1991). As a consequence, genotypes that perform well in one environment may perform poorly under different environmental conditions, and it is unclear whether “generalist” genotypes that perform well under a wide range of conditions, such as those found in Pacific oysters (Langdon et al. 2003), can be found or created in hard clams. In the extreme case, genotype by environment interactions can take the form of strong genetic trade-offs in performance among environments such that good performers in one environment are neces-

*Corresponding author. E-mail: Mark.Camara@oregonstate.edu

sarily poor performers in others, and breeders may have no choice but to develop environment-specific selection lines.

In addition, common procedures in commercial hatcheries such as mass spawning with complete mixing of gametes for fertilization and/or mixing of groups produced through more controlled fertilization procedures combined with aggressive sieving and sorting during the early stages (i.e., larvae, spat and seed) are not conducive to either selective breeding or the conservation of genetic diversity (Dillon & Manzi 1993, Hadley 1993, Newkirk 1978a). These practices contribute to high variance in the contributions of individual parents to the breeding population through either differential fertilization success, larval mortality, or fecundity and can lead to the rapid accumulation of inbreeding, genetic drift, and low effective population size as has been demonstrated in Pacific oysters (Hedgecock & Sly 1990). Unfortunately, if the limited information available from other bivalve species can be extended to hard clams, even relatively low levels of inbreeding may result in substantial reductions in growth and survival (Evans et al. 2004). Commercial-scale hatcheries are typically equipped with a relatively small number of very large tanks for larval culture and thus are poorly equipped to prevent inbreeding beyond attempting to include many parents in the hopes that few are related, and balancing the genetic contributions of parents at the time of fertilization (M. Camara and S. Allen, pers. obs). Unfortunately, a recent study in Pacific oysters (Taris et al. 2006) found that in larval cultures consisting of a mixture of families, the relative contributions of the families could change rapidly, especially if the slow-growing larvae are culled through sieving. In addition, these strategies cannot ameliorate the effects of even infrequent population bottlenecks, and as a result, hatchery strains are likely to have lower genetic diversity and be more inbred than wild populations as has been found in unselected hatchery strains of the Suminoe oyster, *Crassostrea ariakensis* (Zhang et al. 2005) and strains of the Eastern oyster, *Crassostrea virginica* selected for disease resistance (Carlsson et al., in review, Hare et al. 2006). Thus, out-crossing among genetically distinct strains may lead to marked improvement in performance as has been demonstrated in other bivalve species (Hedgecock et al. 2004, Hedgecock et al. 1996).

As a first step toward designing and implementing a genetically rigorous domestication and selective breeding program for hard clams at the Aquaculture Genetics and Breeding Technology Center in Gloucester Point, Virginia, we evaluated the performance of five genetic strains that are used extensively by commercial clam growers in the midAtlantic region of the USA, both as within-strain crosses and in all possible pairwise combinations. Though we have no pedigree information from which to estimate the levels of relatedness among the parents used in any of our crosses, individuals from the same strain are much more likely to be related to each other than individuals from different strains. As a matter of convenience, therefore, we will sometimes refer to the within-cross strains as "pure strains" or "inbred strains" and the among-strain crosses as "hybrids" or "outbred" lines. We deployed all 15 genetic groups across a range of environments chosen to represent the spectrum of conditions under which hard clam aquaculture is practiced in Virginia. This experimental design allowed us to make comparisons of the performance of pure strains to each other, of each pure strain to outcrosses with the other four pure strains, of outcrossed strains derived from different combinations of parental strains and of outcrossed strains to predictions based on additive inheritance from their parental strains. In addition, we were able to

determine if these relationships were stable across varying environmental conditions. Finally, by collecting data on growth and survival at several stages in the life history, we could evaluate the strain-level correlations among characters and the stability of these correlations across environments, to address questions about whether performance in the field was predictable from data gathered in the hatchery or nursery phases of hard-clam culture.

MATERIALS AND METHODS

Broodstock Sources

Researchers in Virginia and New Jersey (Ford et al. 2002, Ragone Calvo & Bureson 2002, Ragone Calvo et al. 2003) have found marked differences in QPX resistance among strains produced in different regions when planted in common garden experiments. Therefore we selected a similar array of stocks for our study. However, because these studies found that the Florida stock they tested was highly susceptible to QPX, and because this finding resulted in a ban on the importation of clam seed from states south of Virginia into Virginia waters (<http://www.nrc.virginia.gov/regulations/fr754.shtml>), we did not use a Florida strain. Clam stocks were obtained from Massachusetts (MA), New Jersey (NJ), and South Carolina (SC), and two from Virginia (KK and VA). All strains except for VA were obtained from commercial hatcheries. The VA strain was the product of early, but limited, domestication efforts at the Virginia Institute of Marine Science (VIMS) led by Michael Castagna.

Spawning, Larval Culture and Field Nursery

All parental animals were brought to the VIMS shellfish hatchery in Wachapreague, Virginia in March of 2000 and brought into reproductive condition by holding them in static tanks at 19°C to 23°C, and feeding them with high concentrations of a mixed diet of 3 species of cultured algae (*Isochrysis galbana*, *Tetraselmis chuii*, and *Chaetoceros neogracilis*). Water was changed three times per week. A few animals were checked weekly for gonadal development and gamete maturity by opening their shells and examining gametes microscopically. Fertilization is external in *M. mercenaria*, and females do not store sperm. Thus, to produce pairwise matings without contamination caused by having males and females in the same spawning raceway, we first determined the sex of individual animals by spawning all parents on 30 March 2001 using a combination fluctuating temperature (Hadley et al. 1997) and the addition of microwave-killed sperm to the spawning trays. We then marked each animal individually and recorded its gender. Males and females were subsequently reconditioned for spawning in separate tanks using the same methods as mentioned earlier. On May 17, 2001, we respawned males and females in separate raceways using the same techniques as mentioned earlier.

We first obtained gametes from each of the parents in separate containers. To accomplish this, at the first sign of spawning, individual parents were removed from the spawning raceway, rinsed several times with filtered seawater, and placed in individual beakers filled with filtered seawater where they continued to release gametes. Males that refused to release sperm were strip-spawned by opening their shells, lacerating the gonads with a scalpel, and rinsing sperm into beakers with filtered seawater. We then combined eggs and sperm to produce the desired crosses among individuals.

To ensure that all groups were as representative as possible of

their parent strains, and that the initial contributions of parents were reasonably balanced, we attempted to produce 20 full-sib families nested within each pure strain and hybrid cross at the time of fertilization and combined them one hour later. Gametes from as many as 10 males and 10 females from each parental strain were collected individually as described above. The eggs from each female were divided into six equal aliquots: one aliquot for each of the four hybrid groups involving that stock and two aliquots for within-strain crosses. Each aliquot was fertilized with sperm from a different male from the appropriate strain to produce full-sib families. For the hybrid groups the different males from each of the two parental strains were randomly paired with an equal number of females from the other strain. The outbred strains were thus represented by up to 20 full-sib families derived from a total of up to 40 parents. Half of these families paired males from one parental strain with females from a second strain, and half paired females from the first strain with males from the second. For the five pure strains, the crosses were slightly different. Because the number of parents within each strain was limited, we used each male and female as parents for two different full-sib families. That is, sperm from each of the males was used to fertilize aliquots of eggs from two different females. As a result, the up to 20 full-sib families within the five pure strain crosses are actually a mixture of full and half-sib families derived from a total of up to 20 parents, each of which contributed to two single-pair crosses. After fertilization was complete, all of the families, representing each pure or hybrid strain, were pooled to form 15 groups representing all possible combinations of the five parental strains. For two of our parental strains, we were unable to spawn 20 parents. Specifically we used only eight males and eight females from the SC stock, and only five males and five females from the VA stock.

Each of the resulting 15 pooled cultures was then split into two 200 L static larval rearing tanks, each containing approximately 1.5 million fertilized eggs to ensure against the loss of cultures and to distribute each group across potential environmental gradients in the hatchery. Tanks were maintained at 25°C and the developing larvae were fed cultured *Isochrysis galbana* twice daily until metamorphosis.

After setting, seed from the two larval tanks for each cross were pooled, and we reared the juveniles first in downwellers and then in upwellers in an outdoor nursery system supplied with unfiltered seawater from the estuary at Wachapreague, VA. On July 20, 2001, when the seed clams had reached about 3–5 mm in shell length, they were transferred to fine mesh spat bags and deployed on the bottom of Cherrystone Creek, VA until October 10, 2001 when they had reached about 10 mm in shell length. At this point, the spat bags were retrieved and the animals from each group were divided into 15 aliquots of 1,250 animals each as estimated volumetrically based on group-specific determinations of volume/count relationships. Poor survival to this point of the VA × VA line permitted only 9 aliquots.

Field Sites and Grow-out

We then deployed the animals at 5 field sites chosen to represent the range of conditions used by commercial clam growers in Virginia. Site locations are shown in Figure 1 and include two high salinity "sea-side" locations in estuaries on the eastern side of the Delmarva peninsula (Quinby and Wachapreague Inlet), two mid-salinity sites in the lower Chesapeake Bay (Hungar's Creek and York River), and one low salinity site (North River). The two

Figure 1. Map showing the locations of the five field sites in the Virginia portion of the Chesapeake Bay.

seaside sites experience high and stable salinity generally between 30‰ and 35‰. Salinity at the York River and Hungar's Creek sites varies seasonally from a low of about 12‰ in spring to nearly 25‰ in fall/winter, (http://www.vims.edu/data_archive/pier/figs/others.html#sal). The North River site is even more variable. Salinities at this site be as low as 0‰ after severe rain events and as high as 25‰ during extended droughts (K. Kurkowski, pers. comm.) At each site, we planted three replicate 1.52 m × 1.52 m plots, each seeded with 1,250 animals that had been previously aliquoted with the exception of the pure VA line, which was not planted at the Hungar's Creek and North River sites. The Wachapreague site was planted on October 11, Quinby on October 12, North River on October 15 and Hungar's Creek and York River on October 16. The 45 plots at each site were arranged in a rectangular grid in a completely randomized design with plots separated by 0.91 m. Each plot was covered with 6.5 mm plastic mesh to exclude predators, and the mesh was held in place by lengths of steel concrete reinforcement bar pressed into the substrate at the edges of the plots as is typical for commercial clam culture in Virginia. Plots were visited regularly to clean and maintain the predator exclusion nets, especially after damaging winter storms.

Sample and Data Collection

Samples of spat and seed were collected and preserved in ethanol at 2 stages in the process: (1) at the end of the nursery stage when the animals were transferred to fine mesh bags in the field, hereafter referred to as "spat" and (2) at the time of field planting, hereafter referred to as "seed." We measured the size of spat using image analysis. Approximately 100 randomly selected spat from each group were spread so that no two were in contact with each other in a clear plastic 150 mm diameter Petri dish placed on a light table and photographed using a digital camera mounted in a copy stand. To minimize parallax error, we positioned the camera approximately 60 cm above the dish and used the camera's zoom lens feature to fill the frame rather than placing the camera close

to the dish. A ruler was included in the frame for calibration. Because of their bilaterally symmetric shape, all spat naturally assume the same position with one valve on the surface of the dish and the other facing the camera. We then used SigmaScan Pro image analysis software (SPSS Inc.) to quantify the area presented to the camera in mm^2 by each of the spat in the digital image. For seed, we measured the shell length and shell width of a random sample of 20 animals from each group to the nearest 0.01 mm using digital calipers. Shell length was defined in this study as the longest dimension of the whole animal in anterior-posterior direction. Shell width was the longest dimension of the whole animal in the lateral dimension. We did not measure shell height (the longest dimension in the dorsal-ventral dimension).

Once the animals were planted in the field, we collected samples from the plots in the Autumn (Oct/Nov) of each year of the study (2002 and 2003). At each sampling date, we removed the net from each plot and removed 4 randomly located 10.2 cm diameter \times 25 cm deep cores of sediment and all of the animals they contained. We sieved each of the cores in the field through 6.5 mm mesh and all live animals and empty shells were collected and counted to estimate the number of live clams in the plot. If we collected fewer than 20 animals in the core samples from any plot, we randomly collected more animals from that plot until we had collected 20 live animals for size measurements. We then brought all the live animals and shells back to the laboratory and measured their shell length and shell width to the nearest 0.01 mm using digital calipers.

Statistical Analyses

All statistical analyses were conducted using SAS version 8 (SAS, 2000). We first examined the frequency distributions and normal probability plots for all of our measurement data and found no marked departures from normality. We, therefore tested for overall differences among the genetic groups in the size of spat and seed using 1-way analysis of variance (ANOVA) with group as the single fixed factor with 15 levels and spat area, seed shell length and seed shell width as response variables. In these analyses, we used the among-individuals residual mean square as the error term in hypothesis tests because mixing the two larval cultures at metamorphosis made them effectively unreplicated.

We followed these ANOVAs with three sets of linear contrasts. The first set of contrasts compared the mean of each of the five pure strains to the pooled mean of the other four outbred strains in which it was represented as a parent. We refer to these as "pure versus hybrid" contrasts. The second set of contrasts ignored the pure lines altogether and for each of the five parental strains, compared the mean of the four hybrid strains to which it contributed to the mean of all 10 outbred lines. These contrasts estimate the average impact of each parental stock on the performance of hybrid progeny, typically referred to as "general combining ability" in analyses of within-population genetic variation (Falconer & Mackay 1996). We refer to these contrasts as general combining ability contrasts even though our experiment involves crosses within and among outbred stocks rather than the more typical inbred lines or individual genotypes. The third set of contrasts tests for nonadditive contributions of the pure parental strains (i.e., dominance and epistasis [Falconer & Mackay 1996]) in outcrossed hybrids by comparing each of the 10 outbred strains to the mean of the two inbred strains from which it was created. For brevity, we refer to these as "mid-parent" contrasts even though we did not

collect any data on the actual parents but rather on the pure parental strains reared simultaneously.

Unlike the larval and nursery stages, each strain was planted in replicated plots at all sites in the field (with the previously noted exception that the VA pure line was not planted at two of the five sites). We therefore tested for differences among-sites and groups in survival (quantified as the number of live animals collected in the core samples) and both of the size-at-age measurements using 2-way ANOVA. The linear model included fixed effects of site and group, site-by-group interaction and, except for survival (which can only be measured on entire plots) a random effect of plot nested within site/group combinations. We also tested for differences between pure and hybrid strains within each of the sites using the same three sets of contrasts as earlier mentioned following separate 1-way analyses of variance for each site with group as the only factor.

To address whether significant site-by-group interactions take the form of strong trade-offs such that groups that perform well in one site tended to perform poorly in other sites, we tested all possible pair-wise correlations between the group means among sites with the expectation that trade-offs would manifest themselves as significant negative correlations.

Finally, because we wanted to determine if performance in the field was predictable from data collected in the hatchery or spat bag stage of culture, we tested for correlations between the group means for spat area and seed length at planting and the group means for survival and shell size measurements at each of the field sites.

RESULTS

Hatchery/Nursery Characters: Spat and Seed Size

There were significant overall differences among the 15 genetic groups in both the mean size of spat as measured by their areas and the mean size of seed as measured by shell length and shell width (Table 1a). Looking first at the spat area data, an examination of Figure 2a reveals that immediately post metamorphosis, the pure NJ \times NJ line produced much larger spat than any of the other groups, that the KK \times KK and MA \times MA pure lines are larger (though less dramatically) than the others, and that all of the outcrossed lines that have the KK strain as one parent tend to be slightly larger than the remaining groups. The pure versus hybrid contrasts (Table 1b) show significant positive effects on spat area of crossing within strains (or conversely negative effects of outcrossing) for the KK, MA and NJ lines, no effect for the SC line, and a significant negative effect of inbreeding for the VA line. The general combining ability contrasts (Table 1c) show that the KK-containing hybrid lines produce significantly larger spat than the average outcrossed strain, consistent with the observation earlier that lines with a KK parent are larger at the spat stage than others (Fig. 2a). In contrast, out-breeding the MA and VA lines to produce hybrids resulted in significantly smaller spat than the average outbred group as indicated by significant negative parameter estimates in the general combining ability contrasts, and hybrid lines that include the NJ or SC line as one parent do not differ from the mean of all outbred groups at the spat stage (Table 1c).

Because seed shell length and seed shell height were highly correlated ($r = 0.995$, data not shown), and produced essentially identical statistical results, we present results for seed shell length only. There are significant differences among the 15 genetic groups in an overall analysis (Table 1a), but these effects are less

TABLE 1.

Analysis of variance results for spat and seed measurements. A. Overall tests of heterogeneity of means of the 15 genetic groups produced. B. Parameter estimate and significance tests of linear contrasts comparing the mean of each pure strain to the mean of the four hybrid strains to which it contributed. Positive parameter estimates indicate that pure lines were superior to hybrid lines. C. Parameter estimates and significance tests of linear contrasts comparing the mean of the four hybrid groups that have the focal group as one parent to the mean of all 10 hybrid groups produced. Positive parameter estimates indicate that the focal line for a given contrast tended to produce superior progeny. D. Parameter estimates and significance tests of linear contrasts comparing each hybrid group to the mean of its two pure strain parental groups. Positive parameter estimates indicate that hybrid strains performed better than the average of the two parental stocks.

A. Overall ANOVA results

Group	Spat area		Seed length	
	F	P	F	P
	69.75	***	24.54	***

B. Pure vs. hybrid contrasts

attributable to the differences seen for the NJ, KK and MA pure lines spat area data. Rather, the most obvious patterns are that all groups that have either a KK or SC parent tend to produce larger seed than those that do not (Fig. 2b). The general combining ability contrasts among outbred strains (Table 1c) confirm this. Seed from KK- and SC-containing hybrid lines were significantly larger than the average outbred strain, and MA- and VA-containing outbred lines were significantly smaller. Contrasts comparing the pure versus hybrid progeny of each parental strain (Table 1b) show significant inbreeding depression of seed shell length in the KK, MA,

VA and SC lines, but these effects are much stronger in the VA and MA lines than in the K and SC strains. There were no significant effects of inbreeding on seed size in the NJ line.

The midparent contrasts (Table 1d) for spat area show significant negative effects for 7 of the 10 hybrid lines indicating that out-crossed spat are typically smaller than the average of their parental stocks. There was also one significant positive effect and two of these contrasts were nonsignificant. For seed shell length, seven of the possible contrasts are significant. All of these significant tests have positive parameter estimates indicating that at the

Plot (Site * Group)	—	—	3.74	***	—	—	3.65	***

ns = not significant, * = $P < 0.05$, ** = $P < 0.01$, *** = $P < 0.001$, — = not testable.

seed stage, most hybrid crosses are larger than expected by additive contributions of the two parental strains.

Field Characters: Size-at-Age and Survival

The overall analyses of variance for the survival and size-at-age measurements (Table 2) reveal that mean survival and shell length in the field differed significantly among field sites and among genetic groups at the Autumn 2002 and Autumn 2003 samplings.

For shell length in Autumn 2002 there was also a significant interaction effect between site and group but not for survival in either year or shell length in 2003. An examination of the pattern of survival in the field among sites reveals that the site effects on survival in 2002 (Fig. 3) are largely caused by much higher survival at the Wachapreague site than all other sites and lower survival of all groups at the Hungar's Creek and Quinby sites, whereas by 2003 the number of survivors is highest at the Quinby site (Fig. 4). It should be noted, however, that these data have some limitations. Our cores samples, for example, captured more live animals in 2003 than in 2002 at the Quinby site. One possible explanation is that the soft, muddy bottom at the Quinby site caused us to under sample these plots in 2002 because the clams were deeper than our core samples. This is, however, very unlikely to have been a problem at other sites where the bottom was firm sand.

For shell length in the field (Fig. 5 and Fig. 6), the significant main effect of sites is largely driven by the larger size of animals at the York River site and smaller size in Hungar's Creek in 2002. In 2003, site effects are less dramatic, partly owing to the loss of the York River site to Hurricane Isabel, but animals at the Quinby, Wachapreague and Hungar's Creek sites are clearly larger overall than at North River.

Pure versus hybrid contrasts for each parental strain at each of the 5 sites (Table 3a) reveal mixed effects. The KK strain showed

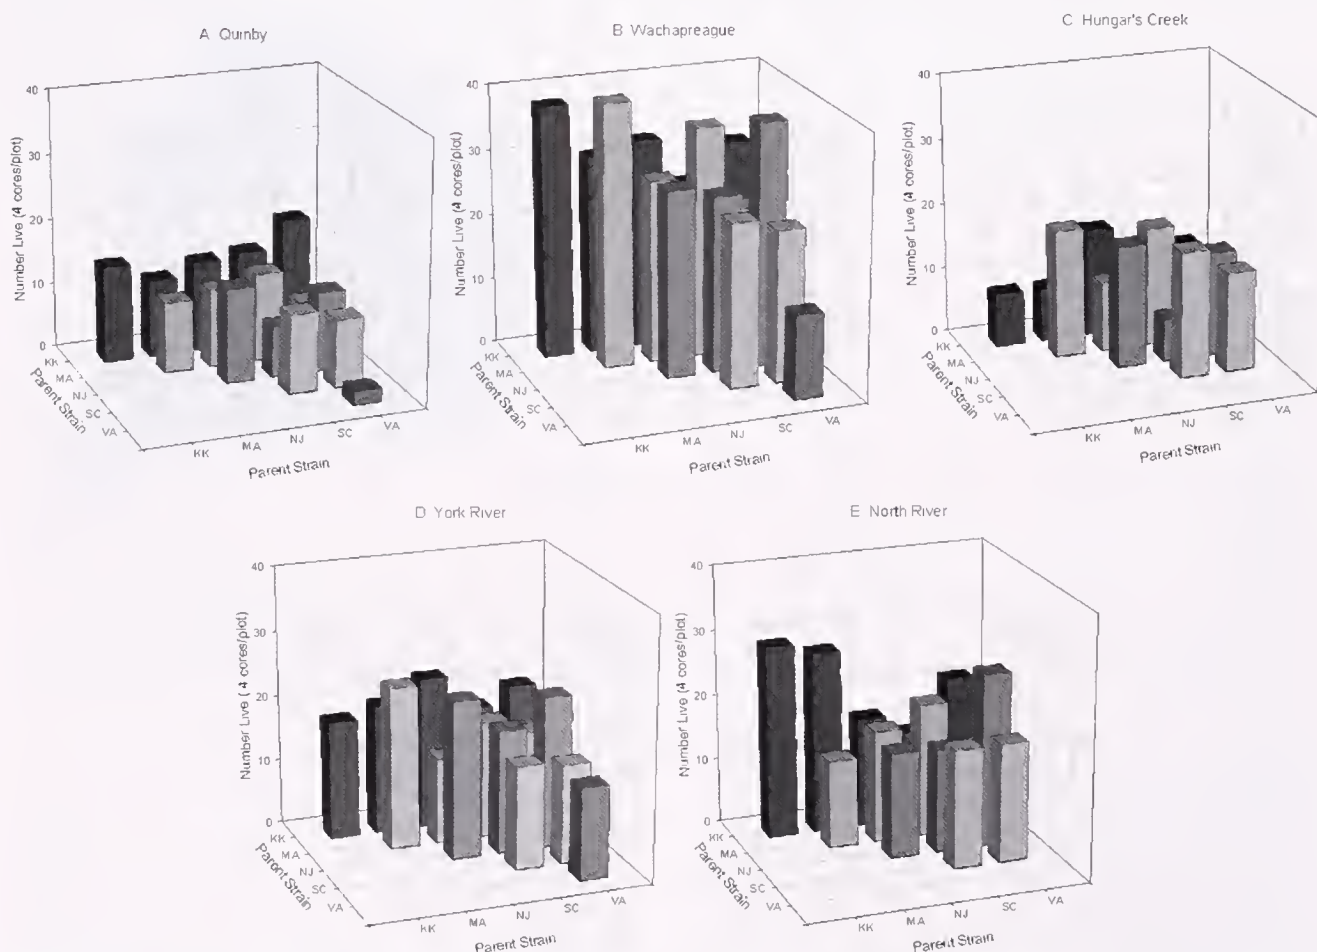

Figure 3. Survival at the Fall 2002 sampling date of all possible combinations of the 5 parental stocks at each of the 5 field sites as represented by the number of live animals collected in the four core samples.

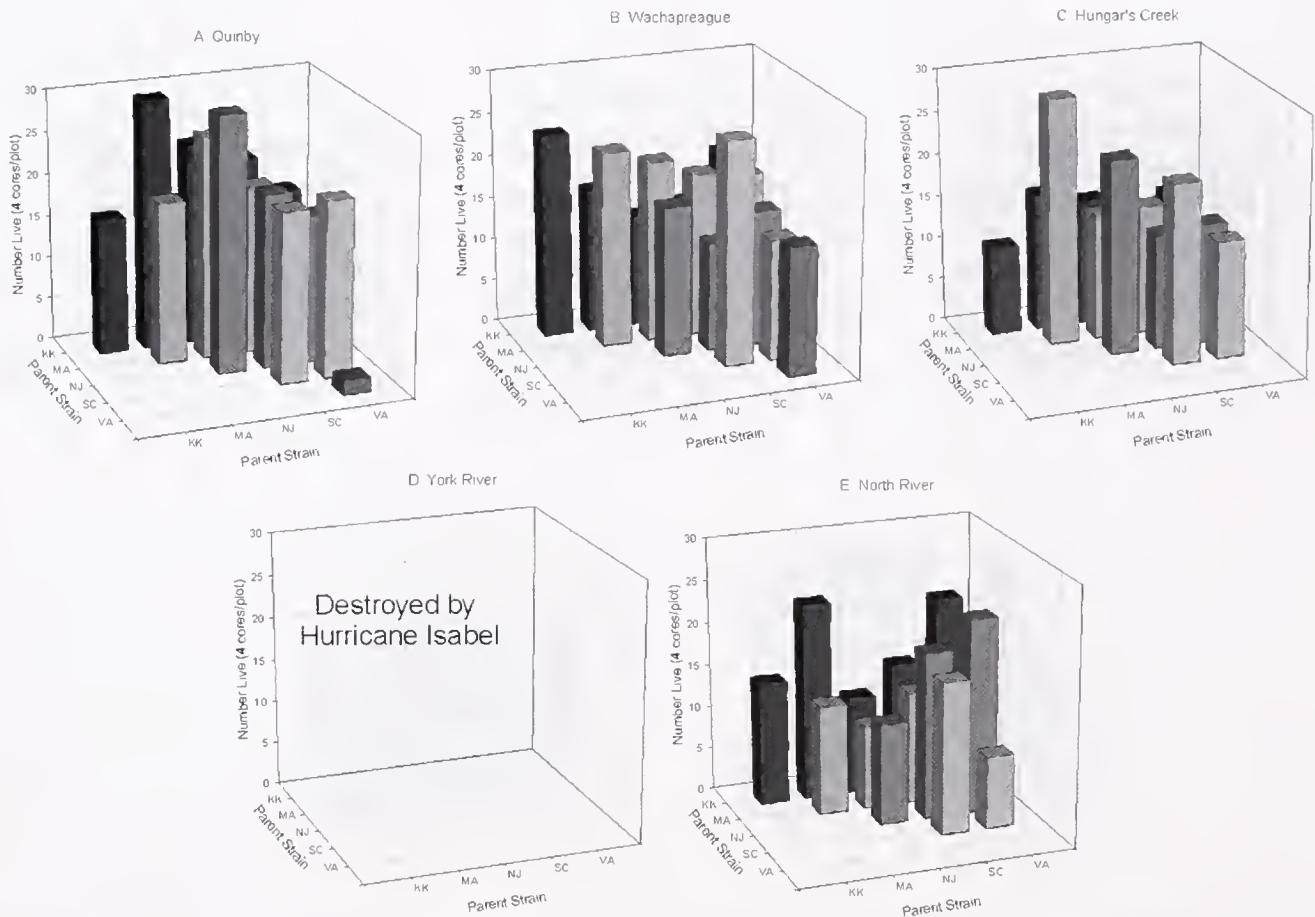

Figure 4. Survival at the Fall 2003 sampling date of all possible combinations of the 5 parental stocks at each of the 5 field sites as represented by the number of live animals collected in the four core samples collected.
